Evaluation of the In vitro and In vivo Antitumor Activity of Histone Deacetylase Inhibitors for the Therapy of Retinoblastoma

Clifton Lee Dalgard, Kurtis R. Van Quill, and Joan M. O’Brien

Abstract

Purpose: To evaluate the potential utility of histone deacetylase inhibitors (HDACi) for treatment of retinoblastoma (RB).

Experimental Design: Growth-inhibitory effects of HDACi [trichostatin A (TSA), suberoylanilide hydroxamic acid (SAHA), or MS-275] were assessed in human and transgenic murine RB cells. Effects of TSA and MS-275 were also assessed in combination with standard therapeutic agents for RB. Proapoptotic effects of MS-275 and TSA were evaluated by caspase-3/7 activity, Annexin V translocation, and/or Bim expression analyses. Effects of MS-275 on cell cycle distribution and reactive oxygen species levels were determined by flow cytometry. Retinal tissue morphology was evaluated in mice after local administration of MS-275. Analysis of retinal acetyl-histone levels was used to assess MS-275 delivery after systemic administration. Therapeutic effects of MS-275 were determined in transgenic mouse and rat ocular xenograft models of RB after i.p. injection of 20 mg/kg every other day for 21 or 13 days, respectively.

Results: TSA, SAHA, and MS-275 dose dependently reduced RB cell survival. TSA and MS-275 showed additive growth-inhibitory effects in combination with carboplatin, etoposide, or vincristine. TSA and MS-275 increased caspase-3/7 activity. MS-275 increased Annexin V membrane translocation and induced G1 arrest. Cytotoxicity of MS-275 was dependent on increased reactive oxygen species levels and was reversed by antioxidant pretreatment. Intracocular administration of 1 μL of 10 μmol/L MS-275 did not alter ocular tissue morphology. Increased acetyl-histone levels confirmed MS-275 delivery to retinal tissue after systemic administration. MS-275 significantly reduced tumor burden in both mouse and rat models of RB.

Conclusions: HDACi should be considered for clinical trials in children with RB.

Cancer is a genetic disease. Tumorigenesis arises from a stepwise accumulation of DNA alterations resulting in gain of function of oncogenes or loss of function of tumor suppressor genes (1). Epigenetic changes, such as DNA methylation and histone acetylation/deacetylation, also contribute to tumor development by regulating the transcriptional activity of genes, including those important for cellular proliferation, differentiation, and survival (2–4). Histone acetylases and histone deacetylases (HDACs) regulate transcription through the transition and removal of acetyl groups on lysine residues at the NH2 terminus of histones, the major protein component of chromatin (5). In general, acetylated histones force chromatin into an open conformational state that promotes gene transcription, whereas deacetylated histones maintain chromatin in a condensed state that silences transcription. Histone acetylases and HDACs target many other proteins in addition to histones (6), and deregulation of these interactions can also be tumorigenic (7, 8). Nonhistone targets of histone acetylases and HDACs include numerous proteins implicated in tumor initiation or progression, including p53, c-MYC, nuclear factor-κB, and E2F.

Retinoblastoma (RB) affects 1 in 15,000 children and accounts for 12% of infant cancers (9, 10). Standard treatment options for this disease are limited and associated with significant toxicities. First-line therapy at most centers includes combination chemotherapy with adjuvant focal therapy (laser therapy, cryo therapy, or brachytherapy). The standard regimen is carboplatin and etoposide or teniposide, with or without vincristine (11). Carboplatin is associated with nephrotoxicity as well as ototoxicity (12), a particularly undesirable outcome in children with this blinding eye disease. Whereas two recent studies have found no association between carboplatin treatment and hearing loss in these patients (13, 14), a 5.6% rate of carboplatin ototoxicity has been reported in children treated at other centers (11). This discrepancy may be attributable to variations in schedule and dosing. Etoposide and teniposide are topoiso merase II inhibitors, which have been associated with the induction of secondary leukemias (15). A recent survey

suggests that RB patients treated with these agents may be at increased risk for this devastating complication (16). In 2007, the National Cancer Institute Children’s Oncology Group opened a phase III clinical trial using periocular carboplatin in addition to three-agent chemotherapy and focal therapy for patients with advanced disease. However, local carboplatin therapy has been associated with reduced ocular motility (17), severe pseudo-preseptal cellulitis (18), and blinding optic atrophy (19, 20). The standard alternative for eye salvage in patients with refractory disease is external beam radiation, yet this therapy increases the already high risk of second primary tumors in patients with heritable disease and produces severe midfacial deformities in these children (21). More rational and less toxic therapies for RB patients are clearly required.

HDAC inhibitors (HDACi) are a promising new class of anticancer therapies (22, 23). Many of these agents, including suberoylanilide hydroxamic acid (SAHA), MS-275, PXD101, and LBH589, have been shown to induce cell cycle arrest, activate differentiation programs, and/or mediate apoptosis in

Fig. 1. Effects of HDACi on RB cellular acetylated histone levels. Western blot analysis of acetylated histone H3 (Lys9) levels in HDACi-treated Y79 cells. After 8 h of exposure to indicated concentrations of HDACi, cell lysates were prepared, and 20 μg protein was electrophoresed, blotted, and probed with the indicated antibodies. A repeat experiment yielded similar results.

Fig. 2. Effects of HDACi on RB cell survival. A. WST-8 tetrazolium dye assay for cell survival in HDACi-treated RB cell lines. After exposure of Y79 (left column) and Weri-Rb1 (right column) cells to the indicated concentration of HDACi for 24, 48, or 72 h, cell survival was determined. Points, mean results of three independent experiments (n = 8 per experiment); bars, SD.
human cancer cells. One HDACi (SAHA, also known as vorinostat) was recently approved for clinical use, and others are currently being investigated in clinical trials for leukemia, lymphoma, and breast, prostate, ovarian, and other cancers (24, 25). HDACi selectively kill tumor cells (26, 27). The molecular basis for the differential effects of HDACi in tumor versus normal cells is not well understood. Recent work has shown that cancer cells with increased E2F1 activity are highly sensitive to HDACi, which target these cells for apoptosis by promoting E2F1-mediated induction of the proapoptotic gene Bim (28). The inactivation of the RB tumor suppressor gene (RB1) leads to increased E2F activity, and this molecular characteristic of RB cells suggests that HDACi could be a particularly rational therapy for this disease. Karasawa and Okisaka (29) conducted the first investigation of HDAC inhibition in RB cells, in which butyrate and trichostatin A (TSA) increased acetylated histone H3 levels, induced apoptosis, and decreased viability in Y79 cells. In this study, we further evaluated the effects of HDAC inhibition in established and primary human RB cell cultures using three HDACi: TSA, SAHA, and MS-275. We also evaluated the effects of MS-275 in vivo in two rodent models of RB to investigate its potential clinical utility.

Materials and Methods

Cell culture. Y79, Weri-Rb1, and Y79-L11C human RB cell lines and Rb143 primary human RB cells were cultured in RPMI 1640 with 10% fetal bovine serum and 1% penicillin-streptomycin. U2OS and SAOS2 human osteosarcoma cell lines and the Rb3 transgenic murine RB cell line were cultured in DMEM with 10% fetal bovine serum and 1% penicillin-streptomycin.

Chemicals and medications. TSA, N-acetylcysteine, and vincristine were purchased from Sigma-Aldrich. SAHA was purchased from Alexis Biochemicals. MS-275 was purchased from Calbiochem. Carboplatin and etoposide were obtained from the inpatient pharmacy at the University of California at San Francisco (San Francisco, CA).

Cell survival assays. For colorimetric analysis, cells were exposed to WST-8 Cell Proliferation Reagent (Dojindo), and absorbance was quantified after 2 h using a SpectraMax microplate reader (Molecular Devices). For bioluminescence analysis (Y79-LUC cells only), cells were exposed to 150 μg/mL D-luciferin, and plates were imaged in an IVIS Imaging System (Xenogen) using a 15-s exposure. Luminescence was quantified using Living Image software (Xenogen). For both assays, cell survival was expressed as a percentage of vehicle-treated control values.

Cell cycle analysis. Cells were washed with PBS and fixed in 70% ethanol overnight at 4°C. Cells were then resuspended in 0.38 mmol/L sodium citrate buffer with propidium iodide and RNase and incubated in the dark at 37°C for 30 min. Cell cycle analysis was done using a FACS-Calibur flow cytometer (Becton Dickinson) and FlowJo software (Tree Star).

Apoptosis assays. For caspase-3/7 activity assay, cells were exposed to Caspase-Glo 3/7 Reagent (Promega) for 30 min at room temperature, and luminescence was quantified using an LMax luminometer (Molecular Devices). Annexin V assays were done using the Annexin V-FITC Apoptosis Detection Kit I (Becton Dickinson). Cells were washed twice with cold PBS and resuspended in binding buffer before addition of Annexin V-FITC and propidium iodide. Cells were
vortexed and incubated for 15 min in the dark at room temperature before analysis using a FACSCalibur flow cytometer and FlowJo software.

**Western blot analysis.** Cells or isolated retinal tissues were washed twice with PBS and resuspended in radioimmunoprecipitation assay buffer with protease inhibitor (Roche) before homogenization. Protein concentrations were quantified using the Bradford method (Bio-Rad), and gel electrophoresis was done using 20 μg protein per lane. Protein was transferred onto nitrocellulose membrane and probed with acetyl-histone H3 (Lys9) antibody (Cell Signaling Technology). Histone H3 (Cell Signaling Technology) or α-tubulin (Santa Cruz Biotechnology) antibodies were used as loading controls.

**Total RNA isolation and gene expression analysis.** Cells were collected and total RNA was isolated using the RNaseasy Mini kit (Qiagen). Total RNA concentrations were quantified by 260/280 spectroscopy using a SmartSpec Plus (Bio-Rad). cDNA was generated using 1 μg total RNA and the iScript kit (Bio-Rad). Bim expression levels were analyzed by real-time quantitative PCR using the iQ SYBR Green Supermix (Bio-Rad) and a MyiQ Real-time PCR Detection System (Bio-Rad). Fold change in expression was determined by comparative cycle threshold (Ct) analysis with normalization against the housekeeping genes HPRT and GAPDH. The following primers were used: human Bim, GAGATATGGATGCCCCAAGA (forward) and CACGGGGCAATG-TAAACCTA (reverse); human HPRT, TGACACTGGCAAAACATGCA (forward) and GGTCTTTTCTCCAGCAAGCT (reverse); and human GAPDH, CATGTCCTATATGACCTT (forward) and GTTGGGAT-TCTTATGTGAC (reverse).

**Reactive oxygen species analysis.** Cells were incubated with 20 μM/L CM-H2DCFDA (Invitrogen) for 30 min at 37°C. Fluorescence was measured using a FACSCalibur flow cytometer, and analysis was performed with FlowJo software.

**Animals.** Two rodent models of RB were used in this study, including the LHβ-Tag transgenic murine model (30) and a recently developed rat ocular xenograft model (31). LHβ-Tag mice carry a transgene composed of the coding region of the SV40 large T antigen (Tag) driven by the promoter of the luteinizing hormone β-subunit gene (LHβ). Tag expression in the retina results in multifocal, bilateral retinal tumors analogous to human RB. For the ocular xenograft model, timed pregnant Wistar rats were purchased from Simonsen Laboratories. Newborn immunonaive pups were injected in the vitreous of the left eye only with 1,000 luciferase-expressing Y79-LUC cells. Animals were screened for tumor burden at P14 by bioluminescent photometry. Animals were first injected with 75 mg/kg p-luciferin (i.p.) and imaged 10 min later in a Xenogen Imaging Station using a 1-min exposure. Tumor burden was then quantified using Living Image software.

**Therapeutic study in LHβ-Tag model.** Two randomized groups of 14 12-week-old LHβ-Tag mice were treated every other day for 21 d with 20 mg/kg MS-275 or DMSO vehicle only (i.p.). Mice were monitored daily and weighed thrice weekly. Animals were sacrificed on day 23, and eyes were enucleated, fixed, and processed to obtain sections daily and weighed thrice weekly. Animals were sacrificed on day 23, and weighed thrice weekly. Tumor burden was quantified on day 13 by bioluminescent photometry, as described above, and a Student’s t test to test for a difference in mean tumor burden between treatment and control groups.

**Therapeutic study in rat ocular xenograft model.** Ten P14 rat pups bearing Y79-LUC ocular xenografts in the left eye only were pair matched by tumor burden and treated every other day for 13 d with 20 mg/kg MS-275 or vehicle only (i.p.). Rats were monitored daily and weighed thrice weekly. Tumor burden was quantified on day 13 by bioluminescent photometry, as described above, and a Student’s t test to test for a difference in mean tumor burden between treatment and control groups.

**Results**

**HDACi increase acetylation of histone H3 in a human RB cell line.** Our initial experiments were done to determine whether three commonly used HDACi, TSA, SAHA, and MS-275, decrease HDAC activity in human RB cells. Y79 cells were treated for 8 h with TSA, SAHA, or MS-275, and cell extracts were analyzed for increased acetylation of histone H3 at Lys9 by Western blot analysis. Increased acetylation was observed beginning at concentrations of 100 nmol/L for TSA, 1 μmol/L for SAHA, and 0.5 μmol/L for MS-275 (Fig. 1). These values are similar to the enzymatic IC50 of these compounds determined in HDAC reactions and to results of similar studies in other human cancer cell types.

**HDACi show potent growth-inhibitory effects in human and murine RB cells.** We next evaluated the growth-inhibitory effects of TSA, SAHA, and MS-275 in human Y79 and Weri-Rb1 cells using the WST-8 colorimetric assay. All three agents showed potent growth-inhibitory effects in Y79 and Weri-Rb1 cells (Fig. 2A). At 72 h after treatment, Gl50 values for each agent in Y79 and Weri-Rb1 cells, respectively, were as follows: TSA, 92 nmol/L and 0.72 μmol/L; SAHA, 2.08 and 1.55 μmol/L; and MS-275, 1.34 and 0.98 μmol/L. These values are similar to concentrations required to increase acetyl-histone H3 levels in our initial experiments. We also tested MS-275 in human RB143 and in transgenic murine Rb3 cells (Fig. 2B). At 72 h, sensitivity of Rb143 cells to MS-275 was similar to that of Y79 and Weri-Rb1 cells (Gl50, 0.85 μmol/L), whereas murine Rb3 cells were significantly less sensitive to this agent (Gl50, 7.2 μmol/L). We also examined HDACi-mediated growth inhibition using a bioluminescent cell survival assay in Y79-LUC cells, which constitutively expresses the luciferase gene. Y79-LUC cells were exposed to TSA and MS-275 for 72 h and imaged after addition of 150 μg/mL d-luciferin. TSA and MS-275 both showed potent growth-inhibitory effects, with Gl50 values similar to those observed in Y79 cells using the WST-8 assay (82 nmol/L for TSA and 1.34 μmol/L for MS-275; Fig. 2C).

**Combining HDACi with carboplatin, etoposide, or vincristine results in additive growth-inhibitory effects in RB cells.**Combination chemotherapy is usually more effective than monotherapy in the treatment of human cancers. We did cell survival assays to determine the potential clinical utility of MS-275 in combination with standard anti-RB agents. Y79 and Weri-Rb1 cells were treated with a single concentration of MS-275 (0.7 μmol/L for Y79 and 3 μmol/L for Weri-Rb1) plus carboplatin, etoposide, or vincristine over a range of concentrations. In both cell lines, combination treatment resulted in a significant, additive reduction in cell survival relative to cells treated with carboplatin, etoposide, or vincristine alone (Fig. 3A). We also tested carboplatin in combination with TSA or MS-275 using the Y79-LUC bioluminescent cell survival assay. Y79-LUC cells were treated with 100 nmol/L TSA or 1 μmol/L MS-275 with or without carboplatin over a range of concentrations. As in our previous experiments, combination treatment resulted in a significant, additive reduction in cell survival relative to cells treated with carboplatin alone (Fig. 3B).

**HDACi induce apoptosis and cell cycle arrest in human RB cells.** To further evaluate the cytotoxic effects of HDACi in RB cells, we did a bioluminescent assay for caspase-3/7 activity (late apoptosis marker) in Y79 cells treated with TSA or
MS-275. Significant increases in caspase activity were observed in cells treated with either agent, relative to controls (Fig. 4A). At 24 h, cells treated with 100 and 200 nmol/L of TSA showed 4.5- and 7.5-fold increases, respectively. Significantly higher increases were observed at 48 h after treatment. In comparison, Y79 cells treated with 5 or 10 μmol/L of MS-275 showed <2-fold increase in caspase activity after 24 h. However, significantly increased activity was observed at 48 h after treatment. Cells treated with 5 and 10 μmol/L of MS-275 showed 5.7- and 5.3-fold increases at this time point, respectively.

Fig. 3. RB cell survival after treatment with HDACi plus carboplatin, etoposide, or vincristine. A, Y79 (left column) or Weri-Rb1 (right column) cells were treated for 48 h with indicated concentrations of carboplatin (CARBO), etoposide (ETO), or vincristine (VIN) with or without MS-275 (0.7 μmol/L for Y79 and 3.0 μmol/L for Weri-Rb1). Cell survival was determined by WST-8 assay. Values are from a representative experiment (n = 4). Bars, SD. A repeat experiment yielded similar results. B, cell survival in carboplatin- and HDACi-treated Y79-LUC cells. Cells were treated for 72 h with carboplatin at the indicated concentrations with or without TSA (100 nmol/L) or MS-275 (1 μmol/L), and luminescence was quantified (n = 12 for TSA, n = 8 for MS-275). Bars, SD. Repeat experiments yielded similar results.
We next examined the effects of MS-275 only on Annexin V translocation (early apoptosis marker) in Y79 cells. Cells were treated with 10 μmol/L MS-275 for 24 h, stained with Annexin V-FITC and propidium iodide, and analyzed by flow cytometry. MS-275–treated cells displayed significant increases in both early and end-stage apoptotic cell populations compared with controls (Fig. 4B). These results suggest that nearly all cells treated with 10 μmol/L MS-275 will undergo cell death, which is consistent with cell survival data in MS-275–treated Y79 cells (Fig. 2A).

We also did cell cycle distribution analysis by flow cytometry in Y79 cells treated with 10 μmol/L MS-275. At 24 h after treatment, cells displayed a significant increase in the G1-phase population and decreases in the S- and G2-phase populations, relative to controls (Fig. 4C). Eighty-two percent of MS-275–treated cells were in G1 phase compared with 55% of cells treated with vehicle alone.

**HDACi-induced apoptosis in RB cells is not mediated by Bim induction.** Other studies have shown that HDACi induce apoptosis in RB1-deficient osteosarcoma cells by promoting...
the induction of Bim, a proapoptotic E2F target gene (28). We began our studies of the mechanisms of HDACi cytotoxicity in RB cells by quantifying Bim expression levels in Y79 cells and in SAOS2 and U2OS osteosarcoma cells after treatment with 100 nmol/L TSA or 1 μmol/L MS-275 for 6 h. Consistent with previous findings, SAOS2 and U2OS cells showed a significant increase in Bim expression after treatment with either TSA or MS-275, but this effect was not observed in Y79 cells (Fig. 5A). Western blot analysis also showed no observable increase in Bim protein levels in TSA-treated Y79 cells relative to controls (data not shown).

**MS-275-mediated cytotoxicity is dependent on increased reactive oxygen species levels.** HDACi treatment in cancer cells has been shown to increase reactive oxygen species (ROS) levels and induce cell death in a manner independent of caspase activation (32). We used CM-H2DCFDA labeling and flow cytometry to measure ROS levels in Y79 cells 24 h after MS-275 treatment (Fig. 5B). Cells treated with 1 and 5 μmol/L of MS-275 showed 3.2- and 10.2-fold higher ROS levels than controls, respectively. These increases in ROS levels could be blocked by pretreatment of cells for 2 h with 7.5 mmol/L N-acetylcysteine, a ROS scavenger. This action resulted in rescue of MS-275 cytotoxicity (Fig. 5C). Forty-eight hours after treatment with MS-275, cells pretreated with N-acetylcysteine showed complete resistance to concentrations as high as 5 μmol/L (GL10 of MS-275 in Y79 cells at 72 h; Fig. 2A).

**Local administration of MS-275 to ocular tissues does not cause morphologic changes.** We investigated the effects of MS-275 on ocular tissue morphology after intraocular administration in mice. Three groups of three adult wild-type animals received intravitreal injections of 1 μL MS-275 (0.1, 1, and 10 μmol/L) or vehicle only. After 2 days, eyes were sectioned, stained with HE, and examined by light microscopy. No change in gross ocular anatomy or morphology in ocular tissues was observed by histologic analysis in any group.

**Retinal delivery of systemically administered MS-275.** Previous animal studies have shown that MS-275 crosses the blood-brain barrier (33). To determine whether MS-275 crosses the blood-retinal barrier, three groups of two adult wild-type mice were treated with 2 or 4 mg MS-275 or vehicle (i.p.). Four hours after treatment, mice were sacrificed, eyes were enucleated, and retina was surgically isolated. Protein extracts were prepared from isolated retina, and acetylated histone H3 (Lys9) levels were determined by Western blot analysis. Retinal extracts from MS-275-treated mice showed a significant increase in acetylated histone levels relative to controls (Fig. 6A).

**MS-275 inhibits RB growth in vivo.** To establish tumors in the rat ocular xenograft model, newborn immunonaive rat pups were injected intravitreally with Y79-LUC cells in the left eye only. Tumor burden was quantified 2 weeks later by bioluminescent photometry. After baseline screening, 10 animals were pair matched by tumor burden and treated with 20 mg/kg MS-275 or vehicle only (i.p.) every other day for 13 days. At completion of treatment on day 13, we observed a significant, 63% reduction in mean tumor burden, whereas all control animals had tumor (Fig. 6C). Figure 6D shows representative sections depicting median tumor burden in MS-275 and control groups (top and middle rows) and tumor regression in MS-275-treated eyes (bottom row).
tumor burden in the MS-275–treated group compared with the vehicle-treated control group ($P = 0.039$; Fig. 6E). Furthermore, each individual MS-275–treated animal possessed lower tumor burden than its pair-matched control animal (Fig. 6F).

**Discussion**

In developed countries, the survival rate among children with intraocular RB is ~95%. However, children who survive this
disease suffer serious morbidity. The great majority of children with unilateral disease are treated by enucleation. Children presenting with bilateral disease are treated with globe salvage therapies, which are associated with serious toxicities. There is currently a great need for the development of improved therapies that minimize adverse effects and maximize preservation of vision in these children. Perhaps, the most promising approach for achieving this goal is to characterize rational therapies with a high therapeutic index that selectively target the molecular abnormalities of RB cells.

Out of the many novel classes of anticancer therapies currently in development, we chose to evaluate the potential utility HDACi for the treatment of RB. Previous research has identified several characteristics of HDACi that suggest that they would be particularly rational therapies for this disease. These agents induce tumor-selective cytotoxic effects (26, 27) and they particularly target tumor cells with deregulated E2F activity (28, 34). Increased E2F activity is a molecular consequence of loss of RB protein function (35), the signature characteristic of RB cells. Furthermore, HDACi are agents that modify gene expression via epigenetic regulation, and RB cells have marked changes in their epigenetic profile (36–39), which are thought to contribute to tumor progression (40). Finally, the antitumor effects of HDACi are synergistic with radiation and with agents currently used to treat RB (41–44). It is therefore possible that the efficacy of current regimens for this disease could be improved by coadministration of a HDACi.

In the present study, we evaluated the growth-inhibitory effects of three first-generation HDACi in RB cell lines. Among the three HDACi tested (TSA, SAHA, and MS-275), we selected MS-275 for further investigation in vitro (apoptosis and cell cycle analyses; drug combination assays) and in vivo (in a transgenic murine and a rat ocular xenograft rat model of RB). Our selection of MS-275 was based on its high therapeutic index, promising results in clinical trials, and availability in amounts sufficient for animal studies. Our animal studies show that MS-275 is a well-tolerated and highly effective treatment for RB in vivo. MS-275 did not alter ocular tissue morphology after intraocular presentation. It readily penetrated the retina after systemic administration, and it significantly reduced tumor burden in both rodent models.

Phase I and II clinical trials have shown that MS-275 also has limited toxicity in humans (45, 46). No grade 4 toxicities were found in patients in a phase I trial of MS-275 administered weekly to patients with refractory solid tumor and lymphoid malignancies (46). The most severe toxicities observed in this trial were reversible or non–dose-limiting grade 3 hypoalbuminemia, hyponatremia, hypophosphatemia, and myelosuppression. MS-275 was also well tolerated in a phase II trial for metastatic melanoma (47). Weekly oral administration of MS-275 resulted in nonobjective tumor stabilization at metastatic locations along with minor grade 1 to 2 diarrhea, nausea, and hypophosphatemia. These data, along with our findings in RB cells that MS-275 induces significant, additive cytotoxic effects when administered with standard anti-RB agents, suggest that HDACi would be a well-tolerated and effective addition to current chemotherapeutic regimens for this disease.

Additional investigation into the mechanisms for selective cytotoxicity of HDACi in RB and other tumor cells is warranted. We observed increased acetylated histone protein levels in both RB cells and normal retinal cells exposed to HDACi. Thus, the underlying reason for high therapeutic index of these agents remains enigmatic. Previous studies have shown that HDACi increase ROS levels in neoplastic cells but not in normal cells (26). Increased ROS levels in HDACi-treated tumor cells could in turn be explained by the finding that HDACi increase levels of thioredoxin, a cellular antioxidant, in normal but not in transformed cells (32). In this study, we found that HDACi cytotoxicity could be rescued in RB cells by antioxidant pretreatment, which may mimic the intrinsic mechanism protecting normal cells. Ungerstedt et al. (32) also found that inhibition of caspase activity did not block HDACi-induced cell death mediated by increased ROS levels. More analysis of this caspase-independent pathway and thioredoxin regulation in RB cells could provide additional insight into the potential responsiveness of RB tumors to HDACi therapy.

Changes in gene expression and regulation may also contribute to the high sensitivity of tumor cells to HDACi. A recent study in RB1-deficient osteosarcoma cells showed that HDACi promote induction of the proapoptotic E2F1 target gene Bim in these cells (28). The authors of this study suggest that this action could explain the heightened sensitivity of
RB/E2F pathway-deregulated tumor cells to HDACi. However, we observed no up-regulation of Bim expression following HDACi treatment of RB cells, which are universally RB1 deficient. HDACi alter the expression of 2% to 5% of all genes, and other E2F target genes could play a role in the apoptosis induction we observed in HDACi-treated RB cells. Further investigation into HDACi-induced gene expression changes could provide additional insight into the molecular mechanisms of HDACi cytotoxicity in RB cells and could help to identify novel molecular targets for future therapies.

Several studies have shown the HDACi induce additive or synergistic effects when administered in combination with other antitumor agents. Other agents that modify gene expression epigenetically, such as demethylating agents, have also shown additive or synergistic effects when combined with other chemotherapies (48). Genes with altered methylation status have been identified in RB tumors, and these alterations have been proposed to be important in tumor progression (36, 40). The antitumor effects of demethylating inhibitors in RB cells, alone and in combination with HDACi or current regimens, should be investigated. HDACi have also been shown to synergize with tumor necrosis factor–related apoptosis-inducing ligand (TRAIL) administration by up-regulating receptor complexes and increasing signaling of the ligand-receptor complexes for activation of death receptor pathways (44, 45, 49). Poulaki et al. (50) have suggested that RB cells are resistant to TRAIL–mediated apoptosis due to silencing of caspase-8 expression. Demethylating agents were able to restore RB cell sensitivity to TRAIL treatment. HDACi may also restore or mediate death receptor pathway activation in RB cells, and these properties should be investigated. Finally, investigations of other HDACi agents in RB, most notably SAHA, LBH569, and valproic acid, should also be conducted. The selectivity of these agents for HDAC isoforms, their pharmacologic profiles, and their therapeutic indices vary, and further work would provide useful information for selection of an optimal agent for the treatment of RB.

The antitumor effects of MS-275 observed in our in vitro and preclinical animal studies are a promising indication that HDACi could provide significant clinical benefits in the treatment of RB. The inclusion of HDACi in combination chemotherapeutic regimens could enable dose reduction of standard broad-spectrum agents, reduction of toxicity, and improved vision retention in children with this disease.

Disclosure of Potential Conflicts of Interest

No potential conflicts of interest were disclosed.

Acknowledgments

We thank Michael A. Dyer, Ph.D., of St. Jude Children’s Research Hospital for his generous gift of Y79-LUC cells.

References

8. Goodman RH, Smolik S. CBP/p300 in cell growth, transformation, and other E2F target genes could play a role in the apoptosis we observed in HDACi-treated RB cells. Further investigations of other HDACi agents in RB, most notably SAHA, LBH569, and valproic acid, should also be conducted.

We thank Michael A. Dyer, Ph.D., of St. Jude Children’s Research Hospital for his generous gift of Y79-LUC cells.
