New Strategies in Prostate Cancer: Targeting Lipogenic Pathways and the Energy Sensor AMPK

Giorgia Zadra¹, Carmen Priolo¹, Akash Patnaik², and Massimo Loda¹,³,⁴

Abstract

Although the role of metabolic syndrome (MS) and a high fat diet in prostate cancer (PCa) risk is still a matter of intense debate, it is becoming increasingly clear that obesity can cause perturbations in metabolic pathways that contribute to the pathogenesis and progression of PCa. Moreover, prostate epithelial cells per se undergo a series of metabolic changes, including an increase in de novo lipogenesis, during the process of tumor formation. These metabolic alterations, at both the cellular and organismal levels, are intertwined with genetic aberrations necessary for neoplastic transformation. Thus, altered metabolism is currently subject to intense research efforts and might provide preventative and therapeutic opportunities, as well as a platform for biomarker development. In this article, we review evidence that the metabolic sensor 5′-AMP-activated protein kinase (AMPK), which physiologically integrates nutritional and hormonal signals and regulates cell survival and growth-related metabolic pathways to preserve intracellular ATP levels, represents a link between energy homeostasis and cancer. Thus, when AMPK is not activated, as in the setting of MS and obesity, systemic metabolic alterations permissive to the development of PCa are allowed to proceed unchecked. Hence, the use of AMPK activators and inhibitors of key lipogenic enzymes may represent a promising therapeutic strategy for PCa.

Background

Prostate cancer (PCa) is the most commonly diagnosed malignancy in men and the second leading cause of cancer-related death in industrialized countries. The main risk factors for this disease are age, black race, and family history. Patients with metastatic PCa initially respond to androgen deprivation (AD) therapy for a median time of 12 to 18 months (1), following which the majority of patients relapse with castrate-resistant disease, which is associated with high morbidity and mortality. Chemotherapeutic treatment options for castrate-resistant PCa have a very modest palliative and survival benefit, so there is clearly an urgent need for additional therapies.

In the era of targeted therapies, many clinical trials have been conducted to test targeted drugs in PCa with the objective of studying their effects either on advanced metastatic disease or on primary tumor (neoadjuvant and surveillance trials). There is now growing interest in targeting metabolic pathways that may be altered during prostate tumorigenesis and PCa progression.

This review briefly discusses the impact of a high-fat diet and the metabolic syndrome (MS) as well as obesity on PCa risk. In addition, some potential mechanistic aspects and intracellular metabolic consequences that might contribute to prostatic carcinogenesis will be discussed. In particular, activation of lipid metabolism has been described in most localized and metastatic prostate tumors, underscoring its potential role in tumorigenesis and tumor progression. Here, we describe the crucial role of 5′-AMP-activated protein kinase (AMPK) as master regulator of lipogenic pathways as well as of intracellular oncogenic signaling [i.e., the mammalian target of rapamycin (mTOR) pathway]. We therefore propose the activation of AMPK as a potential therapeutic strategy in PCa.

On the Horizon

Dietary intervention

The incidence and disease-specific mortality of PCa show marked geographic variation, being greatest in North America and Western Europe, and lowest in Asia (2). These differences undoubtedly have a genetic component, but the relative contribution of diet and the “Western lifestyle” to PCa development has not been elucidated (3). Numerous epidemiological studies support an association between dietary fat intake (particularly saturated fats) and PCa risk (4, 5), unfavorable prognosis, and relapse after treatment for localized PCa (6). In addition, differential
gene expression of human prostate xenografts from mice under high-fat diet showed significant upregulation of insulin-like growth factor 1 receptor (IGF-1R), a known driver of prostatic carcinogenesis, compared with mice under low-fat diet (7). Importantly, however, activating mutations in the IGF-1/phosphoinositol-3-kinase (PI3K) pathway may influence the response of cancers to dietary restriction-mimetic therapies (8). Nevertheless, more recent studies seem to refute these previous observations (9, 10). Thus, the existence of a relationship between fat intake and PCa risk still remains an intriguing open question.

The influence of dietary fat on PCa has been linked to specific fatty acids (FA): several in vivo studies have indicated that low-fat diets high in omega-3 (n-3) polyunsaturated FA (PUFA) reduce the development and progression of PCa, whereas high-fat diets rich in omega-6 (n-6) promote the growth and proliferation of PCa cells (11). Because the “Western diet” contains a disproportionately high n-6 to n-3 ratio, n-6 PUFA is likely to be critical modulators of human prostate carcinogenesis. The tantalizing epidemiological data, combined with the positive effects of n-3 PUFA in cell culture and animal models, prompted the development of clinical trials using n-3 PUFA in the prevention and treatment of PCa (http://clinicaltrials.gov). To date, five clinical trials (NCT0099674, NCT00253643, NCT00458549, NCT00433797, and NCT00402285) are ongoing, and one (NCT00049309) has been successfully completed showing that flaxseed supplementation reduces PCa proliferation rates in men presurgery (12).

Obesity, metabolic syndrome, and PCa

Epidemiological studies. Despite the controversial association between high-fat diet and PCa risk, there is mounting epidemiologic evidence for a relationship between obesity and PCa progression. Obesity has been identified as an important adverse prognostic factor for PCa (13). Moreover, population studies have revealed that PCa patients with higher serum levels of insulin or C-peptide are at increased risk of adverse outcome (14). The mechanism that underlies the association between obesity and PCa is not clear, but insulin-mediated increase of IGF-1 and the subsequent activation of the PI3K/mTOR pathway have been suggested (15). Obesity has also been associated with decreased serum levels of the adipocyte-secreted cytokine adiponectin. Recent epidemiological studies showed an inverse correlation between adiponectin levels and the risk of PCa (16, 17), and in vitro studies confirmed adiponectin’s inhibitory effect on PCa cell growth through activation of AMPK (see below; ref. 18). Moreover, abdominal obesity is frequently associated with MS, a state of metabolic dysregulation characterized mainly by insulin resistance, hyperglycemia, dyslipidemia, hypertension, and predisposition to type II diabetes (19). Even if some studies have shown its association with a higher risk of PCa (20–22), the results are still inconclusive (23, 24). This finding may be due to a lack of unambiguous definition of MS, differences in age at baseline measurement, and length of follow up. In fact, a recent study showed that MS, as defined by strictly accepted international definitions, is significantly associated with PCa mortality when the competing risk of early death from other causes, is taken into account (25).

AMPK. AMPK is a highly conserved energy-sensing serine/threonine kinase, consisting of an α catalytic subunit and regulatory β and γ subunits. At the cellular level, AMPK is activated by metabolic stressors that deplete ATP and increase AMP (e.g., exercise, hypoxia, glucose deprivation). At the level of the organism, enzyme activity is also under the control of hormones and cytokines, such as adiponectin and leptin (26). Activation of AMPK reduces plasma insulin levels, suppresses ATP-consuming metabolic functions (such as synthesis of FAs, sterols, glycogen, and proteins), and increases ATP-producing activities (such as glucose uptake, FA oxidation, and mitochondrial biogenesis) to restore energy homeostasis. Thus, AMPK functions as a central metabolic switch that governs glucose and lipid metabolism.

Decreased AMPK activity has been found to contribute to the metabolic abnormalities involved in MS (15, 27). Moreover, a recent study revealed an association between polymorphisms in the PRKAA2 gene (encoding the α2 subunit of AMPK, which is responsible for the MS phenotype; ref. 28) and susceptibility to insulin resistance and diabetes in the Japanese population (29). Interestingly, the same locus correlates with PCa risk (30), suggesting that AMPK dysregulation may provide a mechanistic link between MS and PCa. Consequently, drugs that ameliorate MS conditions through AMPK activation (Table 1) may be beneficial for PCa prevention and treatment.

Metformin: current and new perspectives. Metformin is a biguanide used as mainstream therapy for type II diabetes for its insulin-sensitizing effects. It has been shown to prevent or delay the onset of MS (31). Recent evidence indicates that: (a) patients with diabetes under treatment with metformin show a reduced cancer incidence (32) and cancer-related mortality compared with patients exposed to sulfonylureas or insulin (33); (b) metformin use is associated with a 44% risk reduction in PCa cases compared with controls in Caucasian men (34); (c) breast cancer patients treated with neoadjuvant chemotherapy and metformin have significantly higher pathologic complete responses than patients not taking metformin (retrospective study; ref. 35). Thus, its potential antineoplastic activity has been proposed and it is currently under investigation. These human studies are further supported by studies in vitro and in xenograft models, showing its antitumor activity on PCa cells (18, 36), and by the exciting discovery that metformin is able to selectively kill cancer stem cells from four genetically distinct breast cancer lines (37). The mechanism of action for metformin’s antitumor effect is not completely understood and has been ascribed to both direct and indirect effect. Metformin’s direct effects on tumor have been partly attributed to AMPK activation (38). At millimolar concentrations,
metformin inhibits complex I of the respiratory chain resulting in increased AMP to ATP ratio and secondary activation of the AMPK pathway (39); this results in inhibition of mTOR and p70S6kinase 1 (S6K1) activity and decreased translational efficiency in PCa cell lines (36). However, inhibition of AMPK using small interfering RNA (siRNA) did not prevent the antiproliferative effect of metformin in PCa cell lines, suggesting that its effects can be independent of AMPK. This result could be partly explained by induction of G0/G1 cell cycle arrest, which is accompanied by a strong decrease in cyclin D1 protein level, pRb phosphorylation, and an increase in p27kip protein expression (36).

In vitro studies have also shown that metformin may inhibit tumor growth by preventing p53-induced autophagy (40), and its treatment has an inhibitory effect on nuclear factor kappa B (NF-κB) and extracellular regulated-signal kinase (Erk) 1/2 activation by an AMPK-independent mechanism (41). Metformin’s indirect effect on tumor proliferation can be explained via inhibition of hepatic gluconeogenesis and increased glucose uptake in skeletal muscle, thereby decreasing circulating glucose, insulin, and IGF-1 levels, and resultant signaling flux through the insulin/IGF-1 pathway (42).

Understanding how biguanides mediate their antican-cer effect is critical before launching trials in metastatic disease. A phase II clinical trial is currently ongoing to study the effect of nonadjuvant metformin therapy in PCa patients prior to radical prostatectomy (NCT00881725). In addition, a randomized phase II surveillance trial to test the combinatorial effect of the 5-alpha-reductase inhibitor dutasteride and metformin in low risk PCa patients, not previously treated, has also been planned at Dana Farber Cancer Institute (Boston, MA).

## Table 1. Current direct and indirect AMPK activators

**Inhibitors of lipogenesis.** ACC, FASN, and HMG-CoA reductase are responsible for the synthesis of malonyl-CoA, the saturated FA palmitate, and mevalonate (the precursor of cholesterol), respectively, and their role in the pathogenesis and progression of PCa is well established (49, 50). Small molecule FASN inhibitors (cerulein, C75, C93, Orlistat), HMG-CoA reductase inhibitors (statins), and ACC inhibitors (such as soraphen A) have shown promising preclinical results both in vitro and in vivo (51–53). So far, the use of FASN inhibitors as systemic drugs has been hampered by pharmacologic limitations and side effects (weight loss; ref. 51). However, recent reports have described new potent FASN inhibitors identified through high-throughput screening as a testimony of the continuous interest for FASN as a therapeutic target (51). Moreover, recent data showed a reduced incidence of PCa among statin users in the Finnish Prostate Cancer Screening Trial, associated with lower PSA levels (54). This evidence suggests that interfering with lipid metabolism represents an important direction to pursue. At present, two clinical trials are ongoing to investigate the effect of statin therapy prior to prostatectomy (NCT00572468) or during external beam radiation therapy (NCT00580970). A more accurate stratification of patients eligible for lipogenic pathway-inhibiting therapies could be achieved thanks to the increasing development of new positron emission tomography (PET)-based metabolic imaging techniques. In fact, lipid metabolism is being investigated by $^{11}$[C]- and

18\textsuperscript{F}-labeled acetate or choline. Both these tracers have shown increased sensitivity in the detection of primary, recurrent, and metastatic PCa (55).

**Direct AMPK activators.** One of the major impediments in the development of targeted therapies is the cross-talk between multiple signaling and metabolic pathways that can result in functional redundancy to maintain cell growth and survival circuits. One strategy to overcome this obstacle is represented by the combinatorial approach to targeted therapies. Another approach may be to target a master regulatory switch of major oncogenic signaling and metabolic pathways, such as AMPK.

The major kinase involved in AMPK activation is the well-known tumor suppressor LKB1 (56). LKB1 germ-line mutations are responsible for Peutz-jegher syndrome, predisposing carriers to hamartomas and a variety of malignant epithelial tumors (57). Interestingly, more than 80% of LKB1 knock out mice seem to develop prostate intraepithelial neoplasia (PIN; ref. 58). This finding suggests that the LKB1-AMPK pathway may act as the link between cancer and energy homeostasis. Indeed, when physiologically or pharmacologically activated, AMPK acts in a tumor suppressor-like fashion. It inhibits key lipogenic enzymes by direct phosphorylation (ACC, HMG-CoA reductase) or by transcriptional regulation (ACLY, FASN) through the suppression of the transcriptional factor sterol regulator element binding protein 1 (SREBP-1). In addition, AMPK inhibits the mTOR pathway through direct phosphorylation of tuberous sclerosis complex 2 protein and the mTOR-associated factor Raptor (Fig. 1). Finally, it induces cell cycle arrest or apoptosis through phosphorylation of p53 and FOXO3a (59). Thus, activated AMPK can switch off multiple oncogenic pathways at once. In particular, it may simultaneously inhibit the two major pathways (lipogenic and PI3K/mTOR pathways) that drive PCa carcinogenesis antagonizing the activity of Akt at multiple levels (SREBP-1, TSC-2, and mTOR complex 1 level). Consequently, AMPK activators, overcoming the feedback activation loop of Akt following long-term mTORC1 inhibition (likely responsible for the clinical failure of mTORC1 inhibitor rapamycin; ref. 60), may be effective in metastatic PCa harboring PTEN deletions. Hence, intense efforts are being made to directly activate AMPK. The direct AMPK activator aminooimidazole-4-carboxamide-1-β-d-ribofuranoside (AICAR), an AMP mimetic, has been shown to inhibit PCa cell proliferation (61) and tumor growth in PCa xenograft models (36). However, AICAR is not entirely specific for AMPK, it has limited oral bioavailability and frequently induces an increase in blood levels of lactic acid and uric acid. The possibility of novel small molecules able to allosterically activate AMPK has been greatly fostered by the recent publication of the crystal structure of AMPK's subunits (62). Abbott laboratories have pioneered this area and identified A-769662, a thienopyridone AMPK activator that activates the enzyme by binding the β1 subunit (63). A-769662 has been shown to delay tumor development and decrease tumor incidence in PTEN+/- mice with a hypomorphic LKB1 allele (64). A second small molecule activator (PT1), not yet well characterized, has also been recently reported (65).

**Conclusion**

The current paradigm in personalized cancer therapies is to target oncogene-addicted pathways in individual tumors. As highlighted in this review, the cellular and whole-organism metabolic milieu can be exploited to interfere with PCa cells using a “synthetic lethal” strategy by combining inhibitors of metabolic enzymes with targeted inhibitors of mutated oncogenes. Furthermore, obtaining broad-based metabolite profiling of prostate tumors by mass spectrometry and/or nuclear magnetic resonance technologies will help develop novel functional PCa classifications on the basis of deregulated metabolic pathways. This strategy, in combination with genetic and proteomic mapping, could be exploited to achieve more accurate subclassification of PCas, new metabolism-based functional imaging techniques, as well as more effective therapies based on targeting metabolic enzymes.
