p27: A Barometer of Signaling Deregulation and Potential Predictor of Response to Targeted Therapies

Seth A. Wander1,2, Dekuang Zhao1,2, and Joyce M. Slingerland1–4

Abstract

Phosphorylation of the cyclin-dependent kinase inhibitor p27 by upstream mitogenic signaling pathways regulates its stability, localization, and biological function. In human cancers, loss of the antiproliferative action of p27 can arise through reduced protein levels and/or cytoplasmic mislocalization, leading to increased cell proliferation and/or cell migration, respectively. Reduced p27 expression levels and p27 mislocalization have potential prognostic and therapeutic implications in various types of human cancers. This review highlights mechanisms of functional deregulation of p27 by oncogenic signaling that provide an important molecular rationale for pathway targeting in cancer treatment.

Background

p27 function and subcellular localization

Cell cycle progression is driven by cyclins and their associated cyclin-dependent kinases (CDK). p27 was discovered as an inhibitor of cyclin E-CDK2 (1–3), but has since been shown to play dual roles to both promote and inhibit cell cycle progression. In G0, p27 translation and protein stability are maximal as it binds and inactivates nuclear cyclin E-CDK2. In early G1, p27 also promotes assembly and nuclear import of D-type cyclin-CDKs (4, 5). The progressive decrease of p27 in G1 permits cyclin E-CDK2 and cyclin A-CDK2 to activate the G1-S transition (6). Mice lacking p27 display multi-organ hyperplasia, increased body size, and susceptibility to carcinogen-induced tumors, suggesting that p27 acts as a tumor suppressor to control both tissue expansion and cell proliferation (7–9).

p27 is regulated at transcriptional, translational, and posttranslational levels (10). p27 mRNA levels usually show little cell cycle periodicity, but may be repressed in a phosphoinositide 3-kinase (PI3K)/AKT–dependent manner (11). In normal cells, p27 protein levels are largely controlled by ubiquitin-dependent proteolysis (6). In early G1, mitogens promote p27 phosphorylation at serine 10 (S10) to facilitate nuclear export (12, 13); this simultaneously relieves cyclin E-CDK2 inhibition and permits Kip1 ubiquitylation-promoting complex (KPC)–mediated proteolysis of cytoplasmic p27 (14). Tyrosine phosphorylation of p27 by BCR-ABL (Y74, Y88, Y99) or src family kinases (Y88 and Y74) impairs the CDK2 inhibitory action of p27. This impairment facilitates subsequent cyclin E-CDK2–dependent T187 phosphorylation of p27, which, in turn, allows it to be targeted by SCFSKP2 for degradation (see Fig. 1; refs. 15, 16). Tyrosine phosphorylation of p27 is also required for the catalytic activation of p27-cyclin D1-CDK4 complexes (17, 18).

Finally, p27 localization seems to be finely tuned during G1 progression. In early G1, as p27 translation decreases, nuclear export of p27 may be needed not only to relieve CDK2 inhibition, but also to promote p27-D type-cyclin-CDK assembly. Transient cytoplasmic retention of newly synthesized p27 is also facilitated in early G1 by PI3K effectors that phosphorylate p27 on T157 and/or T198 to both impair p27 import and promote cyclin D1-CDK4-p27 complex assembly (4).

Oncogenic signaling pathways that disrupt p27 function

In contrast to other tumor suppressors, CDKN1B mutation or deletion is rare in human cancers. Deregulated receptor tyrosine kinases (RTK) activate Src/BCR-ABL and Ras/MEK/ERK kinase (MAPK), or PI3K/AKT signaling, which contribute to oncogenesis by inducing p27 loss or mislocalization, respectively (4, 6).

Cell cycle inhibition is a nuclear p27 function. In many cancers, not only is p27 reduced in the nucleus, but tumors also exhibit different degrees of cytoplasmic p27 mislocalization (19). Cytoplasmic p27 seems to acquire a cell cycle–independent oncogenic function to promote cancer cell invasion. TAT-p27 protein transduction was shown to increase Rac-dependent cell motility (20). p27−/− mouse
embryonic fibroblasts (MEF) show reduced motility compared with wild-type MEFs, which are rescued by reexpression of wild-type p27 or mutant p27 that cannot bind cyclins and CDKs (p27<sup>C<sub>K</sub>−; ref. 21). Thus, the promotility effects of p27 seem to be independent of its cyclin-CDK regulatory functions. In the cytoplasm, p27 binds RhoA to inhibit RhoA-ROCK-mediated actomyosin stabilization (21). Moreover, knock-in of p27<sup>C<sub>K</sub>− increases progenitor cell self-renewal and lung tumor development (22). In malignant lines, overexpression of cytoplasmic p27 increases tumor metastasis in murine models (23, 24) and promotes glioma cell invasion (25). Thus, whereas nuclear p27 inhibits CDK2 to restrain cell cycle, excessive cytoplasmic p27 can have a prooncogenic effect to promote cancer invasion and metastasis.

PI3K is oncogenically activated in many human cancers (26) and not only regulates cell survival, but also modulates cyclin D1, CDK2, p21, and p27 levels and action (27). AKT stabilizes cyclin D1 by inactivating GSK-3β (28). At least three PI3K effectors (AKT, SGK, and RSK) contribute to T157 and T198 phosphorylation of p27 (27, 29–31), which impairs import of monomeric p27 and increases p27-cyclin D-CDK4 assembly (17). Phosphorylation at T198 stabilizes p27 (32, 33), increases its cytoplasmic localization, and mediates p27-RhoA binding and a p27-dependent increase in cell motility (34). Importantly, PI3K/AKT activation is highly correlated with cytoplasmic p27 localization in breast, renal, and thyroid cancers and in certain leukemias (29, 35–37).

mTOR integrates nutrient sensing and mitogenic signals to regulate protein synthesis, cell growth, proliferation, and motility (38). mTOR signaling is linked to that of PI3K (see Fig. 1). AKT-mediated inactivation of the tuberous sclerosis complex (TSC1 and TSC2 proteins) activates mTOR complex 1 (mTORC1, mTOR/Raptor) to upregulate protein biosynthesis required for cell proliferation (38). AKT requires two activating phosphorylations, one via PI3K/PDK1, the second via mTORC2 (mTOR/Rictor; ref. 38). Both mTOR complexes may activate SGK (39, 40). Thus, mTOR-mediated AKT and SGK activation promote p27 phosphorylation at T157/T198, impairing p27 nuclear import and driving cellular proliferation and migration.

Oncogenic RTK and Ras trigger MEK/MAPK activation (41) to mediate either p27 loss or inactivation (42–44). In epithelial cells, transfected oncogenic Ras mislocalized p27 to the cytoplasm and increased p27-cyclin D-CDK4/6 complexes (45). This increase likely reflects constitutive Ras-mediated PI3K activity. Furthermore, Ras-dependent lung tumorigenesis is associated with increased cytoplasmic localization of p27 (46). Constitutively active N-Ras can also mislocalize p27 via the Raf-GEF pathway (47). In fibroblasts, MEK1 overexpression increased p27 degradation, and a MEK1 inhibitor increased p27 stability in one study (48), but led to sequestration of p27 in cyclin D-CDK4 complexes in another (44). In breast cancer cells, p27 proteolysis is activated by HER2 and epidermal growth factor receptor (EGFR) in a MEK/MAPK-dependent manner (42, 49).

Many human cancers have increased Src levels or activity (50), which would increase tyrosine phosphorylation of p27 to promote SCF<sub>SKP2</sub>-mediated p27 proteolysis. In primary human breast cancers, Src activation is associated with reduced p27 protein (15). Similarly, the Src-family kinase, Lyn, and BCR-ABL phosphorylate p27 at Y88, and this is blocked by the ABL kinase inhibitor drug, imatinib (16). To further complicate matters, BCR-ABL was recently reported to promote AKT-mediated phosphorylation of p27 at T157 in chronic myeloid leukemia progenitors leading to increased cytoplasmic p27 (51). Thus, therapeutic interruption of BCR-ABL may not only increase p27 levels, but also restore its nuclear localization.

Constitutive activation of these different oncogenic pathways may contribute to loss of nuclear p27 and increased cytoplasmic p27, both of which drive tumor growth and progression. Reversal of these effects and restoration of the cell cycle inhibitory action of p27 by targeted inhibition of these oncogenic pathways may contribute importantly to the efficacy of targeted therapies for cancer.

**Clinical-Translational Advances**

**Loss of nuclear p27 during tumor progression**

Given the central roles of p27 in cellular proliferation and migration, it is no surprise that reduced or mislocalized p27, documented by immunohistochemical (IHC) analysis in primary tumors, is associated with poor clinical outcome in a diverse variety of human malignancies (6). Progressive p27 loss has been observed during the histopathologic progression of neoplasia from benign, to in situ, and invasive cancers of the breast (52, 53). One study showed that, relative to normal breast duct epithelia in which 95% of cells show high nuclear p27, premalignant atypical ductal hyperplasia shows modest p27 loss (85%), whereas ductal carcinoma in situ (40%) and invasive cancer (34%) show greater p27 loss (53). In ovarian cancer, lesions of low malignant potential showed intermediate p27 levels compared with high levels in normal epithelia, whereas highly aggressive cancers showed very low nuclear p27 (54, 55).

**Immunohistochemical analysis of p27 for prognostication of human cancers**

Reduced p27 nuclear is associated with adverse patient outcome in malignancies of epithelial, hematopoietic, and mesenchymal origin (6). To date, the application of p27 as a clinical prognostic tool has been encumbered by the lack of uniformity in IHC staining protocols. Most IHC studies of p27 have evaluated only nuclear p27, and currently no accepted guideline exists for scoring cutoff values for “low” versus “high.” Despite these limitations, multiple studies show a correlation between reduced nuclear p27 and poor prognosis. This finding has been observed in lung (56–58) and prostate cancers (59–63), and more comprehensively in breast cancer, in which most analyses show reduced p27 is an independent prognostic indicator of disease relapse or death (52, 64–70).
Although far fewer studies have evaluated the prognostic potential of cytoplasmic p27, this is also correlated with adverse outcome in prostate cancer (71), gliomas (72), and high-grade astrocytomas (73). In breast cancer, cytoplasmic p27 staining correlated with AKT activation (29–31) and predicted poor patient prognosis in univariate analysis (29). To date, however, none of these analyses have quantitated both nuclear p27 levels and cytoplasmic p27 mislocalization. An understanding of the potential prognostic and predictive value of p27 (see below) may await this type of study, because reduced nuclear p27 increases proliferation and cytoplasmic p27 would drive tumor cell invasion.

### Targeting critical signal transduction cascades upstream of p27

As reviewed above, diverse oncogenic signaling cascades regulate p27 proteolysis, subcellular localization, and function (see Fig. 1; ref. 4). The informed use of targeted therapies to attenuate deregulated signaling holds tremendous promise for cancer therapy. Several molecular targeting drugs impact p27 by inhibiting upstream signaling. In chronic myelogenous leukemia driven by the BCR-ABL kinase, reduced p27 levels result from its constitutive tyrosine phosphorylation and accelerated proteolysis (16). Treatment of CML cells with imatinib restores p27 levels and inhibits proliferation (16). In many other preclinical models, pathways driving p27 proteolysis were reversed by...
targeted therapies: in Her2-overexpressing breast cancer, p27 proteolysis is attenuated by treatment with trastuzumab (74); the same is true of EGFR-overexpressing lung cancers treated with gefitinib (75). In a recent study, treatment of breast cancer cells with the EGFR/ErbB-2 inhibitor lapatinib increased p27 and reduced tumor proliferation (76). In melanoma models, MEK inhibition increased p27 to induce growth arrest (77, 78). Similar results were obtained using a MEK inhibitor in human pancreatic cancer lines driven by activated Ras (79).

The placement of p27 downstream of various AGC kinases (SGK, RSK, AKT) highlights the tremendous potential for PI3K/mTOR inhibitors to restore normal p27 function. Hyperactivation of PI3K/mTOR signaling, through C-terminal phosphorylation of p27 at T157 and T198, promotes cytoplasmic p27 mislocalization, increased invasiveness, and may underlie progression in a variety of cancers (4). Early clinical trials with rapamycin and its analogs (rapalogs) met with limited success. This result may be due, in part, to incomplete blockade of mTORC1 by rapamycin (80). Furthermore, inhibition of mTORC1 turns on feedback loops leading to PI3K activation (81, 82). This feedback PI3K/AKT activation would promote cytoplasmic p27 sequestration and p27-dependent tumor cell migration and metastasis. Pure mTOR catalytic site inhibitors or dual PI3K/mTOR kinase inhibitors have shown great potential in preclinical models and early clinical trials (83). These new compounds inhibit both mTORC1 and mTORC2, effectively attenuating activation of AGC kinases involved in growth, evasion of apoptosis, cell cycle, and motility (84).

Dual targeting of estrogen receptor and oncogenic Src signaling

In estrogen-responsive tumors, estrogen binding to the estrogen receptor (ER) promotes p27 proteolysis and cyclin E-CDK2 activation, driving cell cycle progression (85, 86). In sensitive ER-positive breast cancers, ER-blocking drugs (tamoxifen and fulvestrant) and aromatase inhibitors oppose estrogen signaling and stabilize p27 to inhibit proliferation and growth. Both preclinical studies (85, 87, 88) and analysis of p27 in breast cancers of patients in clinical trials indicate that high nuclear p27 may predict responsiveness to hormonal therapy (67, 70).

Unfortunately, both de novo and acquired resistance limit the efficacy of hormonal therapies. Oncogenic activation of EGFR family receptors and insulin-like growth factor 1 receptor (IGF-1R) may underlie anti-estrogen resistance, potentially via the Src kinase. Src activation by liganded ER or by oncogenic RTKs in breast cancer (89) would facilitate p27 degradation (16, 90) and oppose growth arrest by anti-estrogens. Recent preclinical studies suggest that combined targeting of both estrogen-ER and Src may prevent the emergence of resistance to anti-estrogens (87, 88, 91). Combined use of an aromatase inhibitor (anastrozole) with an Src inhibitor (saracatinib) in vitro resulted in higher p27 levels and greater G1 arrest, reduced xenograft tumor growth in vivo, and delayed emergence of drug resistance compared with that observed with either drug alone (87). Similar results were obtained using combined saracatinib and fulvestrant (88). Currently, clinical trials are underway to test the potential efficacy of combined Src and aromatase inhibition in postmenopausal ER-positive breast cancer (M. Pegram and J.M. Slingerland, unpublished data). Src activation and/or reduced p27 levels may correlate with de novo lack of responsiveness to ER blockade or aromatase inhibition, and a posttreatment increase in nuclear p27 may predict response to combined therapy as observed in preclinical models. Targeting both Src and ER may prove to have great potential, and a number of Src inhibitor drugs are either approved for clinical use or in clinical development. Furthermore, our knowledge of pathways that disrupt p27 function provides a strong rationale for testing other potential therapeutic combinations. For example, combined ER/MEK blockade or ER/mTOR blockade may both be of clinical value because they would restore p27 function and check tumor proliferation.

p27 as a predictor of therapeutic efficacy

Prognostic studies of tumor biomarkers are valuable as they assist in disease stratification and prompt molecular mechanistic studies that shed light upon the pathways driving tumor progression. However, the most valuable biomarkers are those that reliably indicate response to treatment, acting as predictive markers. In certain contexts, p27 may serve just this purpose. For example, in stage III-IV ovarian cancers, reduced p27 predicted improved patient response to adjuvant platinum-based therapy after surgery (92). This finding likely reflects the efficacy of cell cycle-active chemotherapies in tumors with high proliferation due to low p27. Other studies showed that reduced p27 was associated with poor survival (55, 93). These latter results may reflect the genetic plasticity of rapidly growing tumors giving rise to chemo-resistant clones.

One can envision several scenarios in which aberrant p27 staining in a pretreatment biopsy might guide treatment decisions. Cancers with low nuclear p27 due to enhanced proteolytic degradation may be ideal candidates for Src or MEK inhibitors. In responsive tumors, clinical benefit may correlate with restoration of nuclear p27 staining and reduced tumor proliferation in posttreatment biopsies. Alternately, a pretreatment biopsy showing increased cytoplasmic p27 (with or without low nuclear levels), may herald intratumoral PI3K/mTOR activation and identify tumors most likely to respond to inhibitors of this pathway. PI3K/mTOR inhibitor drugs should shift p27 from cytoplasmic to nuclear localization. A posttreatment increase in nuclear p27 levels (MEK or Src inhibitors) or a shift of p27 from cytoplasm to nucleus (PI3K/mTOR or pure mTOR inhibitors) may prove to be valuable predictors of response to these novel agents. Evaluation of p27 by IHC in pretreatment tumor samples and reassessment of p27 levels and localization in a posttreatment biopsy may prove useful in the initial clinical trials of these new agents. Successful attenuation of PI3K/mTOR signaling with the resulting shift...
from cytoplasmic to nuclear p27 may translate into sub-
stantial clinical benefit, because of reduced cellular inva-
siveness and metastatic potential, whereas restoration of
nuclear p27 action would inhibit tumor proliferation.
Establishing reliable predictors of therapeutic response in
real time will dramatically enhance the clinician’s ability to
diagnose and treat formerly intractable cancers.
