Abstract

**Purpose:** To evaluate safety and activity of perifosine and sorafenib combination therapy in patients with lymphoproliferative diseases.

**Experimental Design:** Patients with relapsed and refractory lymphoproliferative diseases received perifosine (50 mg twice daily) for 1 month. Patients achieving less than partial response (PR) after perifosine alone were administered the combination therapy [perifosine plus sorafenib (400 mg twice daily)] until progressive disease (PD) or unacceptable toxicity occurred. The pERK and pAKT in peripheral blood lymphocytes as well as serum cytokine levels were investigated as predictive biomarkers of response.

**Results:** Forty patients enrolled in this study. After 1 month of perifosine alone, 36 who achieved less than PR went on to combination therapy, whereas four patients with chronic lymphocytic leukemia (CLL) who achieved PR continued with perifosine alone for a median of 10 months (range, 4–21). The most common drug-related toxicities were grade 1–2 anemia (17%), thrombocytopenia (9%), diarrhea (25%), joint pain (22%), and hand–foot skin reaction (25%). Three patients experienced grade 3 pneumonitis. Eight patients (22%) achieved PR, 15 (42%) achieved stable disease, and 13 (36%) experienced PD. A 28% PR rate was recorded for 25 patients with Hodgkin lymphoma. Among all patients, median overall survival and progression-free survival were 16 and 5 months, respectively. Early reductions in pERK and pAKT significantly correlated with the probability of clinical response.

**Conclusions:** Perifosine and sorafenib combination therapy is feasible with manageable toxicity and demonstrates promising activity in patients with Hodgkin lymphoma. The predictive value of pERK and pAKT should be confirmed in a larger patient cohort. Clin Cancer Res; 20(22); 5641–51. ©2014 AACR.
tumor cell growth, proliferation, and survival, which collectively contribute to lymphomagenesis (9–12). On the basis of these findings, a wide spectrum of new agents is currently being tested in patients with lymphoproliferative diseases.

Perifosine (Aeterna Zentaris) is an orally active synthetic alkylphospholipid that inhibits AKT, a protein involved in the PI3K/mTOR pathway (13). Activated AKT phosphorylates a variety of substrates that have a crucial role in cell-cycle regulation. In lymphoma cells, the PI3K pathway is activated by the B-cell receptor (BCR) and exposure to survival factors in the microenvironment (14, 15). Perifosine has been tested as a single agent in phase II/III studies in patients with relapsed/refractory Hodgkin lymphoma. Interestingly, levels of ERK and AKT phosphorylation in peripheral blood lymphocytes were predictive of clinical responses to the combination therapy. Promising activity observed in patients with Hodgkin lymphoma warrants additional clinical trials to evaluate kinase inhibitors in association with new and conventional drugs.

Translational Relevance

Treatment of patients with relapsed/refractory lymphoproliferative diseases represents an unmet medical need that urgently requires development of molecularly targeted agents. We conducted a phase II study testing the AKT inhibitor perifosine in combination with the multitargeted inhibitor sorafenib in patients with relapsed/refractory lymphoproliferative diseases. This is the first study investigating the clinical activity and pharmacodynamic effects of perifosine and sorafenib combination therapy in this patient population. Results of the present study indicate that the combination therapy is feasible and results in clinical responses in heavily pretreated patients, with an objective response rate of 22% among the entire cohort and 28% among patients with relapsed/refractory Hodgkin lymphoma. Interestingly, levels of ERK and AKT phosphorylation in peripheral blood lymphocytes were predictive of clinical responses to the combination therapy. Promising activity observed in patients with Hodgkin lymphoma warrants additional clinical trials to evaluate kinase inhibitors in association with new and conventional drugs.

Antiapoptotic and prosurvival signals in lymphoma cells are derived from the activation of the Ras/Raf/mitogen-activated protein (MAP)/ERK kinase [MEK; or mitogen-activated protein kinase (MAPK)] pathway, which is implicated in cell proliferation, differentiation, and survival in a variety of solid tumors and leukemic cell lines (23–25). Sorafenib (Nexavar; Bayer) is an oral multikinase inhibitor that inhibits the MAPK pathway and several tyrosine kinase receptors involved in angiogenesis and lymphangiogenesis. In lymphoma cells, sorafenib downregulates myeloid cell leukemia-1 (Mcl-1), an antiapoptotic Bcl-2 family member protein implicated in cell survival (25–28). Recently, sorafenib has demonstrated limited antilymphoma activity in patients with lymphoproliferative diseases (29, 30). Complex cross-talk between the PI3K and MAPK pathways suggests that concomitant therapeutic targeting of these signal transduction pathways may have relevant clinical implications (31).

Recent preclinical data have demonstrated that perifosine combined with sorafenib induces gene expression profiling and signaling alterations associated with synergistic cytotoxic activity against lymphoma cell lines in vitro and in vivo, thus providing a strong rationale for evaluating the efficacy of dual-targeted therapy in patients with lymphoma (32).

We therefore conducted a phase II study aimed at evaluating the safety and activity of perifosine and sorafenib combination therapy in patients with relapsed or refractory lymphoproliferative diseases. In addition, this study also investigated a variety of predictive biomarkers, including (i) ERK and AKT phosphorylation in peripheral blood lymphocytes (PBL; refs. 33–35) and (ii) serum levels of cytokines involved in angiogenesis and lymphangiogenesis (36).

Patients and Methods

Patient selection

Patients with advanced lymphoproliferative diseases who had failed second-line or subsequent salvage chemotherapy were enrolled in this study. The eligibility criteria included age ≥18 years, 0–1 Eastern Cooperative Group (ECOG) performance status, and measurable disease as assessed by CT. Adequate renal [creatinine ≤1.5 × upper limit of normal (ULN)], bone marrow (absolute neutrophil count ≥1,000/µL, hemoglobin value >9 g/dL, and platelet count ≥75,000/µL), and liver [serum bilirubin ≤1.5 × ULN, aspartate aminotransferase (AST) and alkaline aminotransferase (ALT) ≤2.5 × ULN, alkaline phosphatase ≤4 × ULN] function was required. Previous chemotherapy, radiotherapy, and surgery must have been completed at least 4 weeks before registration, and autologous or allogeneic SCT must have been completed at least 2 months before registration. Previous sorafenib treatment was permitted. The major exclusion criteria were a history of cardiac disease (i.e., congestive heart failure >NYHA class 2, active coronary artery disease, cardiac arrhythmia, or uncontrolled hypertension), active infection, or symptomatic metastatic brain or meningeal tumor. All patients provided written informed consent in accordance with the Declaration of Helsinki before enrollment in this study. The Institutional Review Board and Ethical Committee approved this study.

Study design and treatment

The primary objective of this open-label, single-center phase II study was to assess the overall response rate (ORR), including the rates of complete remission (CR) and partial remission (PR). The secondary objectives included assessments of safety and tolerability, overall survival (OS), progression-free survival (PFS), time to progression (TTP), and duration of response (DOR). Enrolled patients received therapy with 50 mg twice daily perifosine (kindly provided by Aeterna Zentaris) alone for 1 month followed by a...
response assessment. Patients achieving at least PR with perifosine alone were removed from the study and continued with perifosine treatment until progression of disease (PD) or unacceptable toxicity occurred. Patients achieving less than PR were eligible for perifosine and sorafenib (Nexavar; Bayer AG) combination therapy. On the basis of a previous phase I study evaluating the safety and maximum tolerated dose (MTD) of perifosine and sorafenib combination therapy in renal cell carcinoma (37), patients in our phase II study were administered 400 mg twice daily sorafenib 1 hour before or 2 hours after a meal and 50 mg twice daily perifosine with a meal. The treatment was administered continuously until PD or unacceptable toxicity occurred. In the case of grade 2 perifosine-related clinically significant toxicity, treatment was reduced to 50 mg daily. With regard to grade 3 or 4 toxicity, treatment was withheld until improvement to grade ≤ 1 was achieved. Grade 2 sorafenib-related toxicity required a 200 mg twice daily or 200 mg once-daily dose reduction, whereas grade 3 or 4 toxicity required temporary treatment interruption. After resolution of the related toxicities, dose re-escalation was permitted. If symptoms did not resolve after 3 weeks of treatment interruption, the patients were removed from the study.

**Study assessments**

Tumor assessment by physical examination and CT was performed at baseline, after treatment with perifosine alone, after 4 weeks of combination therapy, and every 8 weeks thereafter. Disease assessment by 218F]fluoro-2-deoxy-D-glucose (FDG)-PET was performed at baseline in stimulated (2ERK and AKT phosphorylation) the treatment.

Events (CTCAE) version 3.0 was used for adverse event (AE) classification. Attributable toxicity was defined as an AE that was classified as possibly, probably, or definitely related to the treatment. The National Cancer Institute Common Toxicity Criteria of Adverse Events (CTCAE) version 3.0 was used for adverse event (AE) classification. Attributable toxicity was defined as an AE that was classified as possibly, probably, or definitely related to the treatment.

**ERK and AKT phosphorylation**

Unstimulated or phorbol 12-myristate 13-acetate (PMA)-stimulated (2 μmol/L; Sigma) PBLs were stained with a phospho-Akt- or phospho-ERK1/2–specific monoclonal antibody (33, 34). Briefly, the cells were fixed with 2% paraformaldehyde for 10 minutes to arrest signaling activity, washed in 2 mL of staining buffer, and permeabilized with 90% methanol at 4°C. The cells were then incubated with an Alexa Fluor 647–conjugated monoclonal antibody specific for S473-phosphorylated Akt and an Alexa Fluor 488–conjugated monoclonal antibody specific for T202/ Y204-phosphorylated ERK1/2 (BD Biosciences). The permeabilized cells were also stained with Alexa Fluor 487- or 488–conjugated mouse immunoglobulin G1 isotype control antibodies (BD Biosciences) to determine background staining. The samples were analyzed with a dual-laser fluorescence-activated cell sorter (FACS Calibur, BD Biosciences) using CellQuest software (BD Biosciences). The results are expressed as the percentage of cells stained with pAkt or pERK1/2 antibody in PMA-stimulated cultures after subtraction of the staining detected in unstimulated PBLs. PBLs from normal donors were also included as an internal control.

**Serum biomarker analysis**

After centrifugation of blood samples at room temperature, sera were frozen and stored at −80°C until use. Custom-made antibody-based chemiluminescent SearchLight multiplex arrays (Aushon BioSystems) were designed to detect and quantify the following soluble molecules: CD40-L, M-CSF, VEGF-A, CD30, TRAIL, and PDGF-AA. In addition to patient sera, a pool of sera from 5 healthy donors was also evaluated for each of these molecules. All serum samples were evaluated in duplicate. Briefly, sera from the patients and controls were incubated with biotinylated antibodies as described previously (36). Next, streptavidin-horseradish peroxidase (SA-HRP) was added. SA-HRP then reacted with a chemiluminescent substrate (SuperSignal ELISA Femto Chemiluminescent Substrate) to produce a chemiluminescent signal that was detected by a CCD camera (SearchLight Plus CCD Imaging System). The SearchLight images were analyzed using Array Analyst software (Aushon BioSystems). Nonlinear regression analysis via Prism software (GraphPad) was then performed to fit the following variable-slope, 4-parameter standard curve equation: \( Y = \text{Bottom} + (\text{Top} - \text{Bottom}) \times (1 + 10^{\left(\frac{\log EC_{50} - X}{\text{HillSlope}}\right)}) \).

**Statistical analysis**

This is a Simon 2-stage phase II study (40). The study was designed to detect a difference of 25% between the null hypothesis proportion of a 15% response rate and the alternative hypothesis of a 40% response rate using a 2-sided hypothesis test with a target significance level of 5% and a power of 90%. After testing the drug in 13 patients in the first stage, the trial would be permanently closed if less than 3 responded. If 3 or more responses were observed, a total of 36 patients would be enrolled to receive the combination therapy. More than 9 responses in 36 patients would be considered evidence that this agent has some activity. Efficacy and toxicity were evaluated in 36 patients...
receiving combination therapy. The ORR was defined as the proportion of patients achieving CR and PR. Time-to-event endpoint distributions were estimated using the Kaplan–Meier method (41). Correlation between changes of ERK and AKT phosphorylation levels during the first 2 months of therapy and the probability of obtaining a clinical response were calculated using the logistic regression model. ANOVA followed by the SNK multiple comparison test was used to compare cytokine levels at different times or in different subgroups of patients. All P values are 2-sided and were considered significant if P ≤ 0.05. The statistical analysis was performed using the statistical package Prism v6.0e (GraphPad Software) on a Macintosh Pro personal computer (Apple Computer, Inc.).

Results

Patient characteristics

From July 2008 to November 2011, 40 patients were enrolled in this study and treated with perifosine alone for 1 month. Four patients with relapsed or refractory CLL achieved PR after treatment with perifosine alone and were not eligible for combination therapy based on the study design. The remaining 36 patients who achieved less than a PR after 1 month of perifosine therapy alone were subsequently administered the combination therapy. The clinical and demographic characteristics of the patients who received combination therapy are summarized in Table 1. Patients had a histologically confirmed diagnosis of relapsed or refractory lymphoproliferative disease, including diffuse large B-cell lymphoma (DLBCL; n = 3), follicular lymphoma (n = 3), CLL (n = 4), Waldenstrom macroglobulinemia (n = 1), and Hodgkin lymphoma (n = 25). The median time from diagnosis to study entry was 5 years (range, 1–15), and the median time since the last therapy was 3 months (range, 1–24). At study entry, patients had undergone a median of 5 (range, 2–11) prior treatment regimens and had relapsed (n = 11) or refractory (n = 25) disease. Refractory disease was defined as a failure to achieve a CR or PR after the last treatment. Twenty-five patients (69%) had undergone autologous SCT, and 15 patients had also received an allogeneic SCT (42%). The majority of patients had advanced-stage disease, with extranodal involvement at study entry in 20 patients (64%). Because 25 of 36 patients receiving the combination therapy had a diagnosis of Hodgkin lymphoma, their clinical characteristics are described in detail in Supplementary Table S1. None of these patients had received Brentuximab Vedotin.

Treatment delivered

Thirty-six patients received at least 1 month of perifosine and sorafenib combination therapy and were evaluated for response and toxicity. The median duration of combination therapy was 4 months (range, 2–18). Because of side effects, 17 patients (47%) required transient sorafenib discontinuation for a median of 7 days. The main reason for discontinuation was grade 3 or prolonged grade 2 hand–foot skin reaction (HFSR; n = 9). In addition, 14 patients (39%) required transient discontinuation of both agents for a median of 7 days. Reasons included gastrointestinal symptoms, fever, skin abscess, blurred vision, ulcerative keratitis, and thrombocytopenia.

The majority of patients (90%) required a transient dose reduction of sorafenib mainly due to gastrointestinal symptoms or HFSR, with 13 patients (42%) requiring a definitive sorafenib dose reduction to 200 mg twice daily. A transient reduction of perifosine, which lasted a median of 10 days, was required in 9 patients (25%) due to grade 2 toxicity (joint pain and gastrointestinal symptoms). Definitive treatment cessation because of disease progression occurred

in 31 patients. Recurrent anorexia with weight loss and grade 3 pneumonitis prompted cessation in 1 and 2 patients, respectively. Two patients with availability of an identical donor discontinued study treatment after achievement of PR and underwent allogeneic SCT.

Treatment efficacy

According to the study design, 4 patients with CLL who achieved a PR after 1 month of perifosine therapy alone were removed from the study and continued perifosine treatment alone for a median of 10 months (range, 4–21). The remaining 36 patients who achieved SD (n = 21) or PD (n = 15) with perifosine alone were administered the combination therapy. Eight of the 36 patients treated with perifosine/sorafenib obtained a PR, with an ORR of 22%. No patients achieved a CR. However, 15 patients (42%) achieved SD, and 13 patients experienced PD. Tumor lesion shrinkage was detected in 7 patients who achieved SD; therefore, a total of 15 patients (42%) exhibited a reduced tumor burden (Fig. 1). The median time to PR was 4 months (range, 1–8). After a median follow-up time of 33 months (range, 22–62), the median OS, PFS, TTP, and DOR for all study patients were 16 (range, 2–62), 5 (range, 2–17), 5 (range, 2–17), and 4 (range, 1–12) months, respectively (Fig. 2). The median OS, PFS, TTP, and DOR for 25 patients with Hodgkin lymphoma were 18 (range, 2–62), 5 (range, 2–17), 5 (range, 2–17), and 3 (range, 1–12) months, respectively. One patient was alive without disease after treatment with perifosine, sorafenib, and allo-SCT, and 12 patients (33%) were alive with disease. In contrast, 22 (61%) patients died from disease progression, and 1 patient (3%) died from pneumonitis. Patients with Hodgkin lymphoma achieving PR or SD by CT scans were also assessed by FDG-PET scans. Of note, in 3 of the 8 SD patients and in 2 of the 7 PR patients, FDG-PET scans displayed necrosis of lymphadenopathy.

PR was observed in patients with Hodgkin lymphoma (n = 7) and CLL (n = 1). The clinical responses according to histologic subtype are detailed in Table 2. Given the promising response to treatment observed among the patients with Hodgkin lymphoma enrolled during the initial study period, we encouraged the inclusion of patients with this histologic subtype. Therefore, the majority of study patients (25 of 36) were affected by Hodgkin lymphoma. Among the patients with Hodgkin lymphoma, 7 obtained a PR (28%), 8 achieved SD (32%), and 10 (40%) experienced PD, with a 60% disease control rate (PR + SD) in this subgroup of patients. The study treatment was the fifth-line or more line of therapy in patients with responding Hodgkin lymphoma. In total, 3 patients were primary refractory, and 4 and 3 patients were classified as refractory and relapsed, respectively, following the last treatment (Supplementary Table S2). Two pretreated patients with Hodgkin lymphoma underwent allo-SCT after achieving a significant PR with perifosine and sorafenib; one of these patients is still in remission 47 months after allo-SCT and the other patient experienced complete remission that lasted 15 months. In patients with Hodgkin lymphoma achieving PR, the median OS was 12 months (range, 5–17) and the time to response ranged from 2 to 9 months. During treatment, median reductions of 75% (range, 53%–81%) and 35% (range, 0%–66%) in serum TARC levels were observed in patients with Hodgkin lymphoma who achieved PR and SD, respectively. A reduction in serum TARC levels was not observed in PD patients.

Safety and tolerability

The AEs that occurred in patients during the first month of treatment with perifosine alone are listed in Supplementary Table S3. The most frequent toxicities were grade 3 increase in AST/ALT values in 3 patients (8%), grade 2 skin abscess in 2 patients (6%), grade 2 fever in 2 patients (6%), and grade 1 skin rash in 2 patients (6%). The hematologic and nonhematologic toxicities recorded during sorafenib and perifosine combination therapy are detailed in Table 3. Hematologic AEs included grade 1 and 2 thrombocytopenia and anemia, which were observed in 9% and 17% of the patients, respectively. Grade 4 neutropenia occurred in 1 patient (3%). The nonhematologic AEs observed in more than 10% of the patients included grade 2 diarrhea (25%), grade 1 weight loss (19%), grade 1 abdominal pain and nausea (11%), grade 1 fever (11%), and grade 2 and 3 HFSR (25% and 14%, respectively). Grade 3 pneumonitis was observed in 3 patients (8%). Unexpected toxicities observed in this study were grade 2 arthritic/joint pain in 8 patients (22%), grade 2 scalp pain in 3 patients (8%), grade 1–2 sterile skin abscess in 4 patients (12%), and grade 2 ulcerative keratitis in one patient. The majority of toxicities were completely reversible after temporary cessation of the study drugs. A patient with HL who had received 4 prior regimens including autologous and allogeneic transplants 3 years before study entry developed pneumonitis 5 months after starting the combination therapy to whom she was responding. This patient had a history of recurrent infections (pneumonitis and cutaneous abscesses) before enrollment and was heavily immunocompromised because of previous transplants and long history of disease. She died...
from sequelae of the pneumonitis (bone marrow and multiorgan failure) 30 days after the last assumption of study drug.

**ERK and AKT phosphorylation**

pERK and pAKT levels were measured in PBLs at baseline and monthly for 4 months in 32 patients who received perifosine/sorafenib therapy. The percentages of pERK- and pAKT-positive PBLs detected in individual patients before therapy are presented in Fig. 3A and B. Values of baseline pERK- and pAKT-positive cells preferentially were above the median values in responsive (PR + SD) and preferentially below in nonresponsive (PD) patients, respectively. Analysis of the continuous distributions of pERK and pAKT values allowed to discriminate responsive and nonresponsive patients ($P = 0.005$ and $P = 0.009$, respectively). Then, the percentage variation between day 60 and 0 in pERK- and pAKT-positive PBLs was calculated for each patient. As shown in Fig. 3C and D, 8 of the 12 patients who experienced PD displayed an increased percentage variation of pERK and pAKT, whereas 18 of the 20 patients who achieved PR and SD displayed reduced percentage variations of pERK and pAKT. Finally, normalized percentage variation values of phosphorylated cells were investigated as a marker of clinical response using logistic regression model. A reduction in the percentage variations correlated well with the probability of response ($P = 0.003$ for pERK and $P = 0.005$ for pAKT).

Serum biomarker analysis

Serum samples obtained from 22 consecutive patients, including 6 PR patients, 8 SD patients, and 8 PD patients, at baseline and at various times during therapy were evaluated using the SearchLight Multiplex array approach. Six of the molecules investigated (CD40-L, M-CSF, VEGF-A, sCD30, TRAIL, and PDGF-AA) were detected in the majority of serum samples from all the patients. None of these factors showed significant changes during therapy that could be associated with response (data not shown). However, after analyzing all available serum samples, we observed that M-CSF, CD30, TRAIL, and PDGF-AA displayed significantly different levels in the 3 response groups (PR vs. SD vs. PD; Supplementary Fig. S1 for CD30 data and Supplementary Table S4 for results for all 4 molecules).

Discussion

In the present study, we assessed the efficacy and tolerability of sorafenib and perifosine dual-targeted therapy in patients with relapsed and refractory lymphoma. Ras/Raf/ MAPK and PI3K/AKT/mTOR are critical pathways in the development and proliferation of lymphoproliferative diseases and solid tumors. Recently, published observations have demonstrated that the blockage/inhibition of only one of the pathways can result in the activation of the other pathway (31, 42). Therefore, on the basis of a specifically...
designed preclinical study (32), we sought to test the effects of concomitant MAPK and AKT inhibition in a clinical setting to investigate the possibility of achieving synergistic activity against lymphoma cells. Results reported herein show a clinical activity of the combination regimen in 8 of 36 patients with a PR being detected in 7 of 25 patients with Hodgkin lymphoma. Despite PFS data suggest a higher activity of perifosine/sorafenib than sorafenib alone (29), no definitive conclusion can be drawn on the comparative efficacy of the single-agent and combination regimen.

We designed the study to assess the therapy in a minimum of 3 patients representing each of the major lymphoma subtypes to determine a target population for subsequent studies. Our initial results demonstrated a significant proportion of clinical responses in the Hodgkin lymphoma group; therefore, we subsequently enrolled primarily patients with Hodgkin lymphoma. The results of the study indicate a 28% ORR and a 60% disease control rate (PR and SD patients) in this histologic subgroup. Overall, the observed ORR of the study was 22%, and the number of patients achieving a clinical response was slightly inferior to the 10 responses requested by the statistical design to demonstrate evidence of some activity of the study drugs. However, although the study design was not planned to investigate activity only in the Hodgkin lymphoma subgroup, it is important to point out the imbalance between the 7 responses observed among 25 patients with Hodgkin lymphoma and absence of responses observed among the remaining patients with NHL. In contrast, we observed significant efficacy with perifosine alone in the patients with CLL; 4 of the 8 patients with CLL responded to perifosine alone, and 1 of the 4 patients who received combination therapy achieved PR. This observation is consistent with recent studies demonstrating either PI3K/AKT pathway activation or anti-PI3K/AKT drug efficacy in CLL. In particular, the activity of the PI3K inhibitor CAL-101 observed in patients with relapsed and refractory CLL suggests that new molecules directed against this pathway should be developed (43). Future clinical trials studying perifosine alone or in combination with other agents in CLL are warranted.

The response rate observed in the Hodgkin lymphoma group is noteworthy given the refractoriness and number of previously administered therapies reported in this patient group. Moreover, the efficacy of the study drugs was confirmed by the clinical history of 2 pretreated patients with Hodgkin lymphoma. In these patients, perifosine and sorafenib treatment acted as a bridge to allogeneic SCT, and the
patients subsequently experienced a considerable amount of time in complete remission. In responsive patients with Hodgkin lymphoma, the observed median PFS of 12 months and the time to response ranging from 2 to 8 months suggest that the antilymphoma activity of the study drugs is not exclusively demonstrated by the achievement of a clinical response. In fact, numerous patients remained on therapy without the development of PD and achieved a PR after many months of unchanged disease. Our findings could be explained by the fact that molecular drugs act on lymphoma cells via slow, continuous activity that inhibits the constitutive proliferative and antiapoptotic signals. In contrast to traditional chemotherapies, molecular drugs do not induce rapid cellular death. These observations along with a recent publication by Younes and colleagues suggest that treatment should not be discontinued when SD is achieved during treatment with targeted agents and that new response criteria are needed (44).

The ORR in patients with Hodgkin lymphoma reported herein is consistent with data from several recent studies investigating the activity of new agents, such as histone deacetylase inhibitors, everolimus and lenalidomide in patients with Hodgkin lymphoma (45–47). In contrast, the new drug-conjugated antibody brentuximab vedotin showed a potent antilymphoma activity, as reported in the pivotal phase II study, the ORR was 75% with 34% of patients achieving CR, patients in complete remission presented a median PFS of 21.7 months, whereas the PFS for all study patients was limited to 5.6 months (48). The antilymphoma activity of these new agents should be confirmed by additional studies investigating methods to optimize the drug combination, timing, and dosing.

The response rate and duration of response reported in this study suggest that dual inhibition is not sufficient to induce durable regression in the majority of patients with lymphoma. This observation can be explained by differences in pathway activation between histologic subtypes as well as patients. The inherent complexity of regulatory growth, proliferation, and survival mechanisms may also be involved. In addition, lymphoma cells can use alternate pathways to escape drug-induced damage. Interesting findings emerged from the Hodgkin lymphoma patient group, suggesting that this subgroup displays increased responsiveness to combination therapy compared with other lymphoma subgroups. We can infer that increased activation of the PI3K and ERK pathways in Hodgkin lymphoma cells could play a role in sensitivity to the study drugs.

The therapy was administered in an outpatient setting, and hospital admissions were limited to one clinical visit per month. The toxicities were mild, and most of the events could be managed by a transient dose reduction. Doses of study drugs were planned on the basis of a recent phase I study conducted in patients with renal cell carcinoma (37); however, in the present study, we observed a higher percentage of patients with hematologic toxicities and nonhematologic recurrent grade 2 toxicities. An increased rate of hematologic toxicity reported in this study is in agreement with our previous observation in patients treated with sorafenib alone and with data reported in patients with DLBCL receiving the kinase inhibitor sunitinib (49). In fact, inhibition of VEGFR, c-kit, and Flt-3 expressed by myeloid and lymphoid marrow progenitors seems to play a role in the pathophysiology of sorafenib-induced marrow toxicity (50). We hypothesize that patients with lymphoma display a reduced tolerance to perifosine/sorafenib combination due to previous extensive exposure to cytotoxic drugs and long history of disease. In particular, the known toxicity of targeted agents on hematopoietic cells when combined with a previous damage induced by chemoradiotherapy might result in an increased hematologic toxicity. Grade 3 or extended grade 2 HFSR, a common sorafenib-related toxicity, represented the main hematologic toxicity causing transient sorafenib discontinuation; patients requiring transient discontinuation of both agents experienced joint pain, skin abscesses, and ocular toxicity. We observed grade 3 pulmonary infections requiring cessation of the therapy in one patient who had received an allogeneic transplant and in a patient with CLL with disease-related immunodeficiency. Although these patients were already immunocompromised because of previous transplant or advanced disease, it is possible that the combination treatment could have contributed to immunodepression. In future studies, the administration of immunoglobulin and antibiotic prophylaxis in CLL and transplanted patients is recommended.

We performed translational analyses of the present study to establish whether serum biomarkers could predict treatment response. Predictive biomarkers are useful for overcoming the risk of poor outcome related to inadequate patient selection in future studies and for optimizing the use of new drugs. The results indicate that pERK and pAKT levels measured in PBLs are predictive of response, decrease of these values after 2 months of therapy indicates a clinical response. Blood biomarkers that indicate the status of ERK and AKT phosphorylation could serve as a simple tool with which to select patients who will benefit from dual-targeted therapy. In contrast, cytokine measurements failed to correlate with clinical response; thus, increased CD30 and M-CSF levels observed in nonresponsive patients most likely reflect the presence of aggressive disease and do not correlate with drug activity.

In conclusion, combination therapy with perifosine and sorafenib exerts antilymphoma activity and is tolerated by heavily pretreated patients with lymphoma. Frequent toxicities such as HFSR and infections did not compromise prolonged treatment but required careful management. The promising clinical responses observed in the patients with relapsed and refractory Hodgkin lymphoma suggest that this subgroup could serve as target population for new studies. Patients who display an early reduction of pERK and pAKT in PBLs could potentially benefit from dual-targeted therapy; thus, this test should be investigated in future studies with a larger patient cohort. The results from
this study encourage the planning of future investigations to assess targeted therapies as well as molecular and conventional drug combinations in patients with lymphoma. Biomarker studies should be included in these new studies to identify responsive patients. The identification of predictive biomarkers could aid in the optimization of new drugs, garner more significant results from phase II studies, and improve the cure rate.

Disclosure of Potential Conflicts of Interest
No potential conflicts of interest were disclosed.

Authors' Contributions
Conception and design: A. Guidetti, C. Carlo-Stella, A. Marchianò
Development of methodology: C. Carlo-Stella, A. Marchianò
Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.): A. Guidetti, C. Carlo-Stella, S.L. Locatelli, R. Mortarini, S. Viviani, D. Russo, R. Sorasio, A. Dodero, L. Farina, M. Di Nicola, A. Anichini, P. Corradini
Analysis and interpretation of data (e.g., statistical analysis, bioinformatics, computational analysis): A. Guidetti, C. Carlo-Stella, S.L. Locatelli, W. Malorni, R. Mortarini, L. Giordano, M. Di Nicola, A. Anichini
Writing, review, and/or revision of the manuscript: A. Guidetti, C. Carlo-Stella, W. Malorni, R. Mortarini, R. Sorasio, L. Farina, M. Di Nicola, A. Anichini, P. Corradini, A.M. Gianni
Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases): C. Carlo-Stella, P. Corradini
Study supervision: A. Guidetti, C. Carlo-Stella, A. Marchianò, A.M. Gianni
