Abstract

Purpose: We undertook this study to determine the prevalence of estrogen receptor (ER) α (ESR1) mutations throughout the natural history of hormone-dependent breast cancer and to delineate the functional roles of the most commonly detected alterations.

Experimental Design: We studied a total of 249 tumor specimens from 208 patients. The specimens include 134 ER-positive (ER+/HER2−) and, as controls, 115 ER-negative (ER−) tumors. The ER+ samples consist of 58 primary breast cancers and 76 metastatic samples. All tumors were sequenced to high unique coverage using next-generation sequencing targeting the coding sequence of the estrogen receptor and an additional 182 cancer-related genes.

Results: Recurring somatic mutations in codons 537 and 538 within the ligand-binding domain of ER were detected in ER− metastatic disease. Overall, the frequency of these mutations was 12% [9/76; 95% confidence interval (CI), 6%–21%] in metastatic tumors and in a subgroup of patients who received an average of 7 lines of treatment the frequency was 20% (5/25; 95% CI, 7%–41%). These mutations were not detected in primary or treatment-naïve ER+ cancer or in any stage of ER− disease. Functional studies in cell line models demonstrate that these mutations render estrogen receptor constitutive activity and confer partial resistance to currently available endocrine treatments.

Conclusions: In this study, we show evidence for the temporal selection of functional ESR1 mutations as potential drivers of endocrine resistance during the progression of ER+ breast cancer. Clin Cancer Res; 20(7); 1757–67. ©2014 AACR.
Translational Relevance
This study demonstrates an overall 12% frequency of somatic ESR1 mutations in metastatic ER+ breast cancer and absence of detectable mutations in the primary tumors. In preclinical models, we show that these mutations render constitutive activity and relative resistance to endocrine therapy. Taken together, these results suggest clonal evolution as the mechanism of resistance. Thus, we propose that these mutations are biomarkers and drivers of endocrine resistance in ER+ metastatic breast cancer. As such, these mutations can assist in clinical decision making as disease progresses, under-scoring the value of serial biopsies and profiling of metastatic recurrences. In addition, further studies are warranted to investigate therapeutic strategies to circumvent the resistance conferred by these mutations.

In most cases of acquired endocrine resistance, ER continues to be expressed. Proposed mechanisms of resistance include activation of growth factor receptor, cell survival and cell-cycle signaling pathways, as well as stress-induced pathways (4, 5). In addition, aberrant expression of ER coactivators and corepressors has been implicated in endocrine resistance (6–7). ER mutations have also been explored as a potential mechanism of drug resistance and initially it was postulated that loss-of-function mutations could contribute to resistance. However, several preclinical studies analyzed the effects of point mutations in ER and found a number of mutations that can actually enhance ER function similar to androgen receptor mutations in castrate-resistant prostate cancer (1–10). One such functional mutation in ESR1 leads to the substitution of tyrosine by serine or alanine at position 537 in the ligand-binding domain (LBD) and results in ligand-independent ER transcriptional activity that does not respond to endocrine manipulation (11–13). Despite these preclinical findings, the frequency of ER mutations in primary breast cancers was found to be extremely rare. In one early study of 118 ER+ and 70 ER- primary breast cancers, only two ESR1 mutations of unknown significance were found and both were in ER- breast cancers (14). More recently, several studies describing next-generation sequencing (NGS) in hundreds of primary breast cancer samples detected multiple significant somatic alterations, but none were detected in ESR1 (11–17). Two small studies conducted in the 1990s detected mutations in the ER LBD with a frequency of 1% to 10% in metastatic breast cancer samples, suggesting that the frequency of ER mutations in metastatic disease may be higher (16, 19). However, these studies were small and had not been validated with more sensitive sequencing technology and/or integrated with clinical correlations. Therefore, in this study, we sought to comprehensively study the frequency and functional significance of ER mutations in both primary and metastatic breast cancer using targeted NGS.

Materials and Methods
Breast cancer human tissue specimens and clinical data
Paraffin-embedded blocks from formalin-fixed ER+/HER2- primary and in-breast local recurrence/metastatic breast cancer specimens were obtained from the Pathology Departments of three institutions (MD Anderson Cancer Center, Houston, TX; Beth Israel Deaconess Medical Center, Boston, MA; and Hospital Clínico Universitario in Valencia, Spain), including samples from the NCT00780676 trial (a phase II trial for patients with advanced metastatic breast cancer treated with dasatinib or selumetinib based on the expression profile of their metastatic tumor). ER+/HER2+ tumors were excluded as they are known to be resistant to endocrine therapy.

All samples were stained for ER, progesterone receptor (PR), and HER2 and reviewed by a pathologist at each institution but were not centrally reviewed. ER positivity was defined as more than 1% of cells with strong staining. Anti-ER antibodies were from Thermo Scientific and Ventana (clone SP1). HER2 was defined as positive either by immunohistochemistry of 3+ or FISH HER2/CEP17 ratio of greater than 2.2. The anti-HER2 antibody was purchased from Dako or Ventana. Clinical data were also collected. For comparison, additional ER- (either ER-/HER2− or ER+/HER2+) primary breast cancer samples were obtained (MD Anderson Cancer Center and Instituto Nacional de Enfermedades Neoplásicas), as well as a small number of specimens from ER- metastatic disease (MD Anderson Cancer Center). Brief descriptions of all studied cohorts can be found in Table 1, and more detailed information about the ER+ metastatic cohort is in Supplementary Table S1. All tissue collections were done with the approval of the corresponding institutional review boards.

Sequencing and primary sequence data analysis
Tumor tissue sections of 40 μm were macrodissected using hematoxylin and eosin staining to identify areas of at least 80% cellularity. Genomic DNA was extracted using the Maxwell 16 FFPE Plus LEV DNA Purification Kit (Promega) and quantified using a PicoGreen fluorescence assay (Invitrogen); ≥50 ng and up to 200 ng of extracted DNA was sheared to approximately 101–400 bp by sonication, followed by end repair, dA addition and ligation of indexed, Illumina sequencing adaptors. Sequencing libraries were hybridization captured using RNA-based baits (Agilent), targeting a total of 3,320 exons of 182 cancer-related genes (most commonly altered in cancer, from http://www.sanger.ac.uk/genetics/CGP/cosmic/) plus 37 introns from 14 genes often rearranged in cancer (Supplementary Table S1). Paired-end sequencing (49 × 49 cycles) was performed using the HiSeq2000 (Illumina). Sequence data from gDNA were mapped to the reference human genome (hg19) using the BWA aligner (20). PCR duplicate read removal and sequence metric collection was performed using Picard (http://picard.sourceforge.net) and SAMtools.
(21). Local alignment optimization was performed using GATK (22).

Genomic alteration detection

Base substitution detection was performed using a Bayesian methodology, which allows detection of novel somatic mutations at low mutation annotation format and increased sensitivity for mutations at hotspot sites (23) through the incorporation of tissue-specific prior expectation: \[ P(\text{Mutation present}) = P(\text{Frequency of mutation } \geq 0|R) \times [1 - P(R|f = 0) P(f = 0)], \]

where \( P(R|f) \) is evaluated with a multinomial distribution of the observed allele counts using empirically observed error rates and \( P(F = 0) \) is the prior expectation of mutation in the tumor type. To detect indels, de novo local assembly in each targeted exon was performed using the de-Bruijn approach (24). Candidate calls are filtered using a series of quality metrics, including strand bias, read location bias, and a custom database of sequencing artifacts derived from normal controls. Germline alterations are identified and filtered using dbSNP (version 135, www.ncbi.nlm.nih.gov/projects/SNP/) and subsequently annotated for known and likely somatic mutations using the COSMIC database (version 62, http://cancer.sanger.ac.uk/cancergenome/projects/cosmic/). Detection of copy number alterations was obtained by performing a log-ratio profile of the sample by normalizing the sequence coverage obtained at all exons against a process-matched normal control. The profile is segmented and interpreted using allele frequencies of exons against a process-matched normal control. The profile sample by normalizing the sequence coverage obtained at all

Luciferase assays

Luciferase reporter assay system (Promega) was used to monitor luciferase activity in 293T cells as per the manufacturer’s recommendations, using a single tube luminometer (BD Monolight 2010). Briefly, \( 1 \times 10^5 \) 293T cells were plated in 6-well plate in hormone-depleted medium. Transient transfections were accomplished using Lipofectamine 2000 (Life Technologies) as per the manufacturer’s protocol.

Site-directed mutagenesis

The GeneArt Site-Directed mutagenesis system (Life Technologies) was used to generate Y537N, Y537C, and D538G mutations within ER LBD. Wild-type ER expression vector (pcDNA-ER) was used as a template with the following mutagenesis primers: Y537N Forward, 5’-AACGTGTCGCCCTCCATGCACCTGCTGCCTGGAGA-3’ Reverse, 5’-ATCTCCAGCAAGCGTGCATTGAGGGGACACCACTT-3’
Western blot and real-time PCR

The following antibodies were used for ER (sc-543, Santa Cruz Biotechnology) and β-Actin (A5441, Sigma) protein detection. For mRNA level measurement, total RNA was prepared using TRIzol reagent (Life Technologies), and cDNA were synthesized using a high-capacity cDNA reverse transcription kit (Applied Biosystems). The following primers were used for GREB1, pS2/TFF1, PR, CA12, β-Actin mRNAs detection, using ABI 7300 Real-time PCR system in combination with PowerSYBR Green PCR Master Mix (Life Technologies):

- GREB1 mRNA: Forward, 5′-CTG CCC CAG AAT GGT TTT TA-3′
- Reverse, 5′-GGG CTG CAG AGC CCA GAA GC-3′

- pS2/TFF1 mRNA: Forward, 5′-GCCAGCtccgggactaatca-3′

- CA12 mRNA:
  - Forward: 5′-GTG GTG TCC ATT TGG CTT TT-3′
  - Reverse: 5′-GTG CAA GTG TCC AGA GA-3′

Results

Sequencing studies

To examine the prevalence and clinical implications of ER mutations in human breast cancer, we assembled a dataset of 249 specimens, obtained from 208 patients, representing both ER+/HER2− and ER− disease (Table 1). The cohorts selected enabled the analysis of the different stages of breast cancer, ranging from diagnostic biopsies of early breast cancers to samples from metastatic recurrences used for biomarker assessment before enrollment in clinical trials. DNA sequencing was performed for 3,230 exons of 182 cancer-related genes plus 37 introns of 14 genes commonly fused on indexed hybridization-captured libraries to an average unique coverage of >500×.

Across the 249 specimens, a total of 16 ESR1 point mutations (substitutions or indels) and 2 instances of locus focal amplification were observed. Although matched normal specimens were unavailable for definitive somatic status determination in our study, a computational assessment of variant allele frequencies supported the germline hypothesis for 4 of 16 observed events (see methods, Supplementary Table S1). Of the remaining 12 somatic variants (Table 2), 9 (75%) occurred at the known recurrent mutation sites in the ER LBD, codons 537/538, while the rest were elsewhere in the LBD (Fig. 1A).

Focusing on the recurrent codon 537/538 LBD mutations, we observed a striking enrichment of these variants in ER− metastatic disease (Fig. 1B): Of the 76 ER− metastatic specimens profiled, the recurring ER LBD mutations were found in 9 (12%) cases. The specific mutations include: Y537N (33%), D538G (33%), Y537S (22%), and Y537C (11%). The prevalence was even higher with a frequency of 20% (5/25 patients) in heavily pretreated patients who received an average of seven lines of treatment, including at least two endocrine treatments for metastatic disease. The mutations were not found in any of the 58 ER+ primary treatment-naive tumors or the 115 ER− tumors.

Our study included 37 matched primary and metastatic pairs. In two of these pairs, EM8 and EM11 the point mutations Y537C and D538G were detected in the metastatic samples but not in the matching untreated primary tumors. For one patient with a mutation (sample EM43), we were able to sequence tissue from an earlier metastatic specimen. Both biopsies were from the same metastatic site but were attained at two time points from a patient who did not receive adjuvant hormonal treatment. The first metastatic lesion, without a detectable ESR1 mutation, was obtained before the initiation of tamoxifen and the second one, found to have a Y537C mutation, was obtained at the time of disease progression after 8 years of treatment. Finally, in 3 specimens, codon 537/538 mutations exhibited allele frequencies consistent with subclonal cell populations. Collectively, these findings suggest a clonal selection of an endocrine-resistant phenotype.

We then broadened our analysis to the genomic context of ER alterations by examining the full spectrum of genomic alterations in primary and metastatic ER− disease. The list of the 182 genes that were sequenced can be found in Supplementary Table S3. All 25 advanced metastatic, as well as 46 early metastatic and primary, specimens were considered in this analysis. A similar analysis of the other 63 ER+ specimens has been presented previously (28). ER alterations were not mutually exclusive with any other commonly altered gene in ER− breast cancer (P53, PIK3CA, CCND1, MYC, FGFR1, MCL1), although HER2 copy gains could not be assessed in our dataset as clinical ER+/HER2+ cases were excluded. Nonetheless, we believe more samples will be needed to verify this observation (Supplementary Fig. S1). Of the most frequently altered genes (altered in >5 samples), all but ESR1 alterations displayed similar frequencies across primary and metastatic specimens, suggesting a role for aberrant ER in the development of recurrent disease (Fig. 2).

Functional studies

To delineate the functional roles of the mutations in codons 537/538 found in metastatic breast cancer patient samples, we performed site-directed mutagenesis to prepare three ER expression constructs containing 2 different amino acid substitutions at position 537 (Y537C and Y537N) and one amino acid substitution at position D538 (D538G). All ER mutations were confirmed by sequencing. The constitutive activity of the Y537N and Y537S mutations has been

established previously (11, 19). To assess the transcriptional activity of the Y537C, Y537N, and D538G mutants we transiently transfected ER−/− breast cancer cells with wild-type (WT) ER or the mutant ER constructs and an estrogen-responsive promoter-reporter construct, ERE-TK-Luc (Fig. 3). Cells were treated with either control vehicle or estradiol (E2) and luciferase activity was measured. As expected, the WT-ER construct exhibited activity only with E2 stimulation. In contrast, all three ER mutants possessed constitutive activity in the absence of E2 stimulation, whereas the addition of E2 did not increase the reporter activity significantly. In addition, both the ligand and nonligand–dependent activity in the mutants was higher than the ligand-stimulated activity of the WT-ER. We next treated the cells with increasing doses of 4-hydroxytamoxifen or fulvestrant with or without E2. Cells expressing the WT-ER responded to 4-hydroxytamoxifen and fulvestrant with a significant and dose-dependent reduction in luciferase activity. The ER mutants also responded to 4-hydroxytamoxifen and fulvestrant in a dose-dependent manner; however, the mutant ER displayed a significantly reduced response to all doses of antiestrogens except for the highest dose of 4-hydroxytamoxifen. Mutant ER exhibited decreased response to 4-hydroxytamoxifen and fulvestrant and higher doses of these antiestrogens were required to achieve the level of inhibition seen in the WT receptor. To confirm the decreased response of the mutant ER to fulvestrant, we examined ER degradation after 24 hours with increasing doses of fulvestrant. As we expected, mutant ER degradation compared with WT-ER was less pronounced at all doses of fulvestrant tested (Fig. 3C). In addition, since it has been shown that endocrine-resistant breast cancer can respond to estrogen treatment (29, 30), we tested the response of the Y537N and D538G mutants to a wide range of E2 levels but did not detect a significant change in the luciferase activity (Supplementary Fig. S2). These results suggest that the ER mutants would be relatively resistant to established clinical doses of tamoxifen and fulvestrant as well as estrogen treatment and higher doses of SERMs or newer selective estrogen receptor degraders (SERDS) with improved pharmacokinetics may be required to inhibit mutant ER activity.

To study the transcriptional activity of the ER mutant in ER−/− breast cancer cells, we transfected a WT-ER construct and the Y537N construct in MCF7 cells. WT and mutant ER signaling was measured by determining the expression levels of ER regulated transcripts with or without E2. As shown in Fig. 4A, PR, GREB1, CA12, and PS2 transcript levels were comparable between the WT and ER-mutant in full media, whereas in E2-deprived conditions these ER-regulated genes are induced by the Y537N mutant but not the WT-ER. In addition, when we examined cell proliferation in estrogen-deprived conditions, which mimic aromatase inhibitor treatment, as well as treatment with 4-hydroxytamoxifen or fulvestrant, we found a significant growth advantage for the Y537N mutant (Fig. 4B). These results demonstrate that cells expressing the Y537N mutant exhibit constitutive transcriptional activity of ER target genes and an abrogated growth inhibitory response to E2 deprivation, tamoxifen, or fulvestrant treatment.

Discussion

The advances in sequencing technologies over the past few years have led to a new paradigm in the understanding of the mutational landscape of breast cancer and tumor
heterogeneity. In this study, we performed targeted NGS, which enables high levels of sequencing coverage to detect low frequency mutations within limited cellular populations, in order to study ER mutations in breast cancer. In this study, which is an international effort, we assembled a large sample set of breast cancers comprised primarily of ER$^+$/HER2$^-$ metastatic samples and associated treatment histories as well as ER$^+$ primary tumors and control ER$^-$ tumors. The majority of the ER$^-$ metastatic samples were obtained from patients who received at least one form of endocrine treatment, to focus on endocrine-resistant tumors.

In this report, we detected in 11 of the 76 (14%) metastatic tumors ESR1 mutations in the LBD. Nine of these mutations are substitution mutations affecting Y537 and D538. In addition, we identified two mutations, 344insC and E380Q, that were not described in the literature previously and further studies are needed to test their clinical significance.

Figure 3. Analysis of the transcriptional activity of the recurring mutant ER and dose response to tamoxifen and fulvestrant. A, transient transfection of 293T cells with WT or mutant ER expression vectors in addition to ERE-TK-Luc reporter vector. ER expression levels were determined to be equivalent by Western blot analysis. ß-Actin expression level is shown as an internal loading control (left). Luciferase activity comparison of transfected 293T cells then treated for 24 hours with 10 nmol/L estrogen (E$_2$) or vehicle (ethanol) for 24 hours. Experiments were done in triplicates and repeated three times. Data represent mean ± SD and are normalized by ß-galactosidase internal control activity (left). B, luciferase activity comparison of 293 T cells transfected with WT or mutant ER expression vectors in addition to ERE-TK-Luc reporter vector, then treated with vehicle (ethanol) or indicated dose of E$_2$ and increasing doses of 4-hydroxytamoxifen (4-OHT) or fulvestrant (Fulv) for 24 hours. Response to 4-OHT and fulvestrant is normalized to the response to E$_2$ stimulation. Data represent mean ± SD and are normalized by ß-galactosidase internal control activity. An unpaired two-tailed t test was used to examine the statistical differences between the WT and Y537N mutant, and P values are shown. C, R levels determined by immunoblotting 24 hours after treatment with increasing doses of fulvestrant.
functional significance. In line with our data, other groups have recently identified the Y537 and D538 mutations and additional other mutations (31–34). The mutations detected in these studies are clustered in the LBD in a substantial number of metastatic ER$^+$ cancers. Among these three studies, the largest cohorts consisted of 36 and 44 metastatic tumors with a mutation frequency of 25% and 11%, respectively, supporting the significance of these mutations in advanced disease. We did not detect LBD ESR1 mutations in 58 primary ER$^+$ tumors and is consistent with the findings of The Cancer Genome Atlas of more than 450 cases (35). In contrast, LBD mutations were detected in 3% of the primary tumors from the BOLERO 2 study, where patients with ER$^+$ metastatic breast cancer that had progressed in the metastatic setting were randomized to exemestane ± the TORC1 inhibitor everolimus (32, 36). This discrepancy may be due to the fact that the primary tumors in the BOLERO 2 represent a selective group of patients who all developed resistance to endocrine treatment, among them approximately 20% developed resistance early after adjuvant hormonal adjuvant treatment. Thus, the frequency of the recurrent ESR1 LBD mutations in primary disease remains an open and important question, as the existence of these mutations in early disease has important implications for the selection of adjuvant treatment for thousands of patients annually.
The recurring LBD mutations in positions Y537 and D538 are at the start of helix 12, a highly conserved α-helix that undergoes conformational changes during ER activation. Therefore, it is not surprising that mutations in these positions would have functional implications. Similar to previous studies that focused on the Y537N, Y537S, and D538A mutations (11, 19, 37), our functional studies indicate that the Y537N, Y537C, and D538G mutations lead to ligand-independent activity that is relatively resistant to tamoxifen, fulvestrant, and estrogen deprivation. Prior studies led by Katzenellenbogen and colleagues have shed light on the mechanisms of these findings by demonstrating that the ER mutants that confer constitutive activity adopt a conformation that resembles the WT ligand-bound ER and the Y537S mutant has a decreased affinity to E2 with increased binding to coactivators (12, 38). The mutant ER affinity to tamoxifen and fulvestrant has not been tested; however, we hypothesize that it is also reduced and together with increased coactivator binding leads to the relative resistance to these drugs. Our studies show that higher doses of tamoxifen or fulvestrant are able to partially decrease the mutant transcriptional activity, suggesting the possibility that higher doses of these agents could be a strategy to circumvent this relative resistance. This might explain in part the results of the CONFIRM trial in which a higher dose of fulvestrant improved progression-free survival (39). Further experiments to understand the detailed mechanism of the endocrine resistance of these mutants and test this hypothesis are under way.

Previous studies in xenograft models of MCF7 cells demonstrated the emergence of a D351Y LBD mutation in a tamoxifen-resistant and stimulated tumor (40, 41). In this study, we analyzed tumor specimens obtained at different stages of ER+ breast cancer, including primary treatment-naive primary disease, local recurrent and/or metastatic disease with an average of two lines of treatment for metastatic disease, and metastatic disease biopsied after an average of seven treatments. The frequencies of the recurring ER-LBD mutations in these three cohorts were 0%, 8%, and 20%, respectively, demonstrating a correlation between the increase in the frequency of these mutations and tumor progression. In addition, in a case from which serial biopsies were available, we were able to detect the emergence of the LBD mutation as the patient developed resistance to tamoxifen treatment. Taken together, these findings suggest a temporal evolution of ER mutations with emergence of an endocrine-resistant phenotype.

In our study, we detected ESR1 amplifications in a primary and metastatic tumor. Multiple studies have investigated the frequency of ESR1 amplifications in ER+ primary breast cancer though the data have been controversial. Two large studies found ESR1 amplifications in approximately 20% of cancers, which correlated with an increased response to tamoxifen, whereas in other studies, amplifications were detected in just 1% to 3% of tumors (41–45). Our study is consistent with the latter studies as we observed an ESR1 amplification rate of 1.7% (1/58) in primary ER+ tumors. Similarly, the frequency of amplifications in metastatic samples was also very low (1.3%, 1/76). This is the first study to report the frequency of ESR1 amplifications in metastatic breast cancer.

In summary, our study demonstrates an overall 14% frequency of somatic ESR1 mutations in a large cohort of metastatic ER+ breast cancers though the retrospective nature of our study limits our ability to precisely determine the frequency. The absence of detectable mutations in the primary tumors suggests clonal evolution as the mechanism of resistance. Thus, we propose that these mutations are a genomic mechanism of endocrine resistance. As such, the detection of these mutations can assist in clinical decision making as disease progresses, underscoring the value of serial biopsies and profiling of metastatic recurrences. In addition, since the frequencies of these mutations are substantial when sensitive testing methods are used in patients with ER+ breast cancer, studies to identify alternative dosing schedules of currently approved antiestrogens and novel therapeutics that can overcome this resistance are warranted.
