ABSTRACT

We have shown previously that melanoma cells in culture release heavy-chain ferritin (H-Ferritin) into supernatants and that this is responsible for the suppression of responses of peripheral blood lymphocytes stimulated by anti-CD3. These effects were mediated by activation of regulatory T cells to produce interleukin (IL)-10. In the present study, we examined whether a similar relation might exist between levels of H-Ferritin and activation of regulatory T cells in patients with melanoma. Ferritin levels were evaluated by ELISA and regulatory T-cell numbers were assessed by three-color flow cytometry to identify CD4⁺ CD25⁺ CD69⁺ T cells. CD69 positive cells were excluded to avoid inclusion of normal activated CD4, CD25 expressing T cells. Measurements of H- and light-chain (L)-Ferritin by ELISA revealed that H- but not L-Ferritin was elevated in the circulation of melanoma patients. In addition, these studies revealed a marked increase in the number of CD4⁺ CD25⁺ CD69⁺ T cells in such patients, compared with age-matched controls. The ratio of H-Ferritin:L-Ferritin correlated with the levels of regulatory T cells consistent with a causal relation between unbound H-Ferritin levels and the activation of regulatory T cells. H-Ferritin or regulatory T cells did not, however, correlate with the stage of the melanoma. These results provide evidence for the importance of H-Ferritin in the induction of regulatory T cells in patients with melanoma and provide additional insight into the suppression of immune responses in such patients.

INTRODUCTION

Ferritin is a major tissue iron-storage protein (1) and, in its native form, has a molecular weight of $M_r \approx$500,000. It is composed of 24 subunits consisting of acid/H³ and basic/L chains (2, 3). The 24-subunit polymer may form iso-ferritins, which are either more acidic (H-rich) or more basic (L-rich) depending on the relative proportions of H and L chains. Liver and spleen ferritins are basic because they are made up mainly of L chains and very few H chains. In contrast, heart, kidney, and placental ferritins are highly acidic because they are composed of mostly H chains (4). The ferritin found in cancer cells was found to consist mainly of H chains (5, 6). Ferritin is localized predominantly intracellular; however, small amounts are present in plasma (7), urine (8), cerebrospinal fluid (9), ascitic fluid (10), milk (11), and all body fluids thus far tested (12), which suggests that it is actively secreted by cells.

A number of functions have been attributed to the extracellular ferritins: regulation of myelopoiesis (13), regulation of lymphocyte migration (14), and as an immunosuppressive agent (15). The immunological and structural properties of extracellular ferritin vary in different fluids (12), which probably relates to its origin and function. A large body of evidence indicates that the level of plasma ferritin parallels the concentration of storage iron within the body, regardless of the cell type in which it is stored (16). This relationship of plasma ferritin to body iron stores, however, is altered in inflammatory states and liver disease, conditions in which ferritin is disproportionately elevated (17). Elevated levels have also been reported in the plasma of patients with different malignancies; however, the source of the ferritin is unknown (18–20). We have previously shown that there was marked variability found in the ratios of H-Ferritin: L-Ferritin released from melanoma cultures. It was shown that some melanoma cells released predominantly H-Ferritin, whereas others contained more equal proportions of H- and L-Ferritin (21).

In addition, we have previously shown that H-Ferritin from melanoma cells may suppress immune responses (21). This was attributable to changes in antigen presenting cells, which resulted in the preferential activation of regulatory T cells that produce interleukin 10 (22). The regulatory T cell implicated in this suppression appeared to be a particular subpopulation of CD4⁺ T cells, which constitutively express the CD25 component of the interleukin 2 receptor and the CTLA-4 T cell activation receptor for CD80 (B7.1) and CD86 (B7.2; Refs.

23–27), CD4+ T cells with this phenotype have been previously shown to suppress autoimmune disease in several animal models (28, 29) and to facilitate the survival of transplants (30–32) and hence their description as CD4+CD25+ regulatory T cells.

Elevated levels of CD4+CD25+ regulatory T cells have been described in a number of cancers including patients with lung, ovarian (33), breast, and pancreatic carcinoma (34).

In view of these findings, the present study examined whether H-Ferritin levels were elevated in patients with melanoma and whether the relation between H-Ferritin and regulatory T cells shown in vitro may also apply in patients with melanoma.

MATERIALS AND METHODS

Patients. Blood was collected from 30 melanoma patients attending either the Sydney or the Newcastle Melanoma Units. Details on the patients are described in Table 1. Clinically evident disease was present in nine of the patients. Blood was also collected from 19 age-matched subjects with no history of melanoma. Included among the control subjects were eight patients attending the Royal Newcastle Dermatology Clinic for non-melanoma-related conditions (Table 2). The median age for melanoma patients and normal subjects was 60 and 53 years, respectively.

Antibodies and Recombinant Proteins. The MAbs RH02 and LF03, specific for human H- and L-Ferritin, respectively, was kindly provided by Dr. Paolo Arosio (Università di Brescia, Brescia, Italy) and are described elsewhere (35, 36). Anti-CD3 was the OKT3 MAb (37). The MAb against CD25 was purchased from Endogen, (Woburn, MA). The MAbs against CD3, CD4, CD8, CD14, CD45RO, CD56, CD69, CD152 (CTLA-4), and IgG1 isotype were purchased from PharMingen, (San Diego, CA). The MAb against PD-1 was purchased from Santa Cruz Biotechnology (Santa Cruz, CA). The polyclonal antibody against placenta ferritin was purchased from Fitzgerald (Concord, MA). Recombinant H-Ferritin (rH-Ferritin) and L-Ferritin (rL-Ferritin) was kindly provided by Dr. Paolo Arosio and is described elsewhere (38, 39).

Blood Samples. For collection of plasma, blood was collected in 4-ml vacutainers containing 7.2 mg of K2 EDTA (Becton Dickinson, San Jose, CA). The plasma was separated from packed blood cells by centrifugation at 500 g for 10 min at 20°C. The plasma was then stored in aliquots at −80°C.

For studies on lymphocytes, blood was defibrinated on glass beads and lymphocytes (PBL) separated by centrifugation on Ficoll-Paque gradient (Amersham Pharmacia Biotech, Buckinghamshire, England) as described previously (22).

Preparation of T-Cell Subpopulations. PBLs were re-suspended in DMEM, containing 10% FCS (CSL Biosciences, Sydney, New South Wales, Australia), and adherent cells were removed by adherence in 75-cm2 plastic flasks (Sarstedt, Newton, NC) for 2 h in a 37°C incubator supplemented with 5%
CD25+ or CD69+ cells were enriched or depleted by positive or negative selection, respectively, on midMACS columns (Miltenyi Biotec, Bergisch-Gladbach, Germany). In brief, nonadherent PBLs were first incubated with anti-CD25 or CD69 MAb for 30 min on ice in PBS-2 mM EDTA (Sigma, St. Louis, MO) supplemented with 1% human AB plasma and then were incubated in the same buffer with antimouse IgG1 MicroBeads (Miltenyi Biotec) for 15 min. The cell suspension was then added to a miniMACS column for 5 min and was washed four times with PBS-2 mM EDTA. Isolation positive fraction, the column was removed from the magnetic field, and the cells were eluted with PBS-2 mM EDTA. Isolation of CD69−CD25+ cells required a two-step isolation process, involving a CD69-negative selection followed by a CD25-positive isolation. The purified T-cell populations were treated with 25 μg/ml mitomycin-C (Kyowa Hakko Kogyo CO., Ltd., Tokyo, Japan) at 37°C for 1 h, before being added to the proliferation assay.

**Proliferation Assay.** Proliferation assays were set up as described by Gray et al. (21). Briefly, 2 × 10⁵ PBLs were cultured with 1 × 10⁵ or a 2-fold dilution (1 × 10⁵ to 3.125 × 10⁵) of mitomycin-C (Kyowa Hakko Kogyo CO.).-treated CD25−CD69− cells in 200 μl of DMEM containing 10% FCS (CSL Biosciences) in a 96-well U-bottomed plate (Falcon, Becton Dickinson, Franklin Lakes, NJ). For blocking studies, MAb against CTLA-4 was prebound to the plate with 10 μg/ml anti-CD3 in carbonate buffer [0.1 M NaHCO₃ (pH 8.2)] overnight at 4°C. Cultures were then incubated in a 37°C incubator supplemented with 5% CO₂ for 72 h. Two μCi of [5-¹²⁵I]iodo-2(1-deoxyuridine ([¹²⁵I]UDR; Amersham, Aylesbury, United Kingdom) was added for the final 4 h before cell harvesting. [¹²⁵I]UDR incorporation was then measured on a Compu-Gamma CS gamma counter (Wallac, Oy, Finland). The degree of inhibition of anti-CD3 stimulation was calculated as described elsewhere (40).

**Ferritin ELISA.** The ferritin ELISA was set up similar to methods described by Vaisman et al. (41). Optimum concentrations for rabbit polyclonal anti-Ferritin (placenta), RH02, LF03, and biotin-labeled rabbit antihuman immunoglobulin antibodies were determined using a checkerboard ELISA assay. In brief, 100 μl of rabbit polyclonal anti-Ferritin (placenta) at 2 μg/ml in coating buffer [0.1 M NaHCO₃ (pH 8.2)] was added per well in a 96-well plate (Maxisorp Nunc, Copenhagen, Denmark), which was sealed using an acetate plate sealer (ICN Biomedicals, Aurora, OH) and was incubated overnight at 4°C. The plate was washed three times with PBS-Tween (500 μl of Tween 20 to 1 liter of PBS) and then was blocked with 200 μl of PBS-Tween-1% BSA (Sigma, St. Louis, MO)-10% FCS and was added to each well (100 μl) and incubated (sealed) for 1 h at room temperature. The plate was washed six times with PBS-Tween; 100 μl of RH02 or LF03 MAb (2 μg/ml) for H- or L-Ferritin detection, respectively, was placed in each well for 90 min (sealed) at room temperature. The plate was subsequently washed six times with PBS-Tween before the addition of 100 μl of biotin-rabbit antihuman immunoglobulin (1:2000) and was incubated (sealed) for 1 h at room temperature. The plate was washed an additional six times with PBS-Tween, the plasma or standards (100 μl diluted in PBS-Tween-0.5% BSA-10% FCS) were added and incubated (sealed) overnight at 4°C. The plate was washed six times with PBS-Tween; and 100 μl of RH02 or LF03 MAb (2 μg/ml) for H- or L-Ferritin detection, respectively, was placed in each well for 30 min at room temperature. The plate was then washed eight times with PBS-Tween, and 100 μl of ABTS [300 μg/ml; 2,2'-azino-bis (3-ethylbenzthiazoline-6-sulfonic acid), 0.1 M citric acid (pH 4.35), 3% H₂O₂ (added before use)] were placed in

*b* Detection using ferritin ELISA.

*n.a., not available.
each well; the reaction was allowed to develop for 10–80 min. The plate was read at A405 nm. The concentration of ferritin in each sample was calculated from the log/linear regression curve obtained from the standard. The linear region of the standard curve was between 15 and 500 ng/ml. For samples with greater concentrations, a dilution of the sample was assayed.

**IFN-γ ELISA.** An anti-CD3 proliferation assay was set as previously described. After 24 h, the supernatants were collected from the proliferation assay. IFN-γ was assayed using a biotinylated ELISA system (PharMingen) according to the manufacturer’s instructions.

**Flow Cytometry.** Analysis was carried out using a Becton and Dickinson (Mountain View, CA) Facscan flow cytometer. Appropriate concentrations of MAbS were added to the cells in 100 μl of PBS (containing 1% human plasma, and the cells were incubated for 30 min at 4°C. Cells were washed twice with PBS and were analyzed. For indirect labeling, cells were incubated with F(ab')2 fragment affinity-isolated phycoerythrin-conjugated sheep antimouse (Silenus; Amrad Biotech, Boronia, Victoria) or FITC rabbit antigen immunoglobulin (Chemicon International, Inc., Temecula, CA) plus 1% human plasma for 30 min at 4°C. Cells were then washed once in PBS before analysis. A minimum of 5000 cells were analyzed by flow cytometry. The percentage of positive cells was calculated as the difference in positive area between the positive and negative control histograms. The positive area was that to the right of the intersection of the two curves (42).

**RESULTS**

**Definition of CD4+ CD25+ CD69− Regulatory T Cells in Blood of Normal Subjects and Melanoma Patients.** CD25+ T cells within an unstimulated PBL population isolated from a normal subject was found to be 84.7% CD4+, 5.5% CD8−, and 9.7% CD4− CD8− T cells. The CD25+ cells also expressed CD3, CTLA-4, CD45RO, and PD-1 (83.5, 87.0, 68.4, and 86.0% of CD25+ cells, respectively), but not CD14 or CD56 (1.6 and 2.8% of CD25+ cells, respectively).

CD4+ CD25+ T cells may also represent normal activated CD4+ T cells. We were concerned that this population may be present at higher levels in patients with melanoma and may give rise to falsely high levels of regulatory T cells. For this reason CD4+ CD25+ T cells that also expressed the CD69 activation antigen were excluded. Detection of CD4+ CD25+ CD69+ T cells in a melanoma patient using three-color flow cytometry analysis is shown in Fig. 1a. Sixteen % of the unstimulated PBLs were CD4+ CD25+ and 1.7% were CD4− CD25+. In addition it shows that 31.2% of CD4+ T cells were CD25+, and of these, 22.6% were CD69+. Therefore, the number of CD4+ CD25+ T cells expressing CD69+ was 7%, indicating that the number of CD4+ CD25+ CD69− regulatory T cells made up 24.2% of the unstimulated CD4+ T cell population. The different functional properties of CD4+ CD69− and CD4 CD69+ cells from a normal subject are shown in Fig. 2. CD4 CD69+ cells stimulated the anti-CD3 stimulated PBL response, whereas CD4 CD69− cells inhibited this response. Similarly, anti-CD3-stimulated IFN-γ production was increased in the presence of CD4 CD69− cells but was inhibited by CD4 CD69+ cells.

The percentage of unstimulated CD4+ T cells with a CD4+ CD25+ C69− or CD69+ phenotype in PBLs from 20 melanoma patients and 14 normal subjects is shown in Fig. 1b. The patients and controls used in this study are described in Tables 1 and 2, respectively. There was a significant elevation in the level of CD4+ CD25+ C69− regulatory T cells in melanoma patients in comparison with the control subjects tested (P = 0.007, by paired t test). The median percentage of CD4+ T cells with a CD4+ CD25+ C69+ phenotype was 14.7% for melanoma patients and 9.1% for normal subjects. Two samples from the control subjects with the above average levels of CD4+ CD25+ C69− had been treated for basal cell carcinoma (subjects 15 and 17). There was also a (nonsignificant) trend for CD4 CD69+ cells to be increased in patients with melanoma.

The suppressive effects of CD25+ CD69− regulatory T cells were investigated in an unstimulated PBL population isolated from a normal subject. The patients and controls used in the study are described in Table 1. CD25+ CD69− regulatory T cells from a normal control subject were isolated by immunomagnetic bead separation. Supernatants were assayed for IFN-γ using a biotinylated ELISA system (PharMingen) according to the manufacturer’s instructions. An anti-CD3 proliferation assay was set up and the supernatants were assayed for IFN-γ using an ELISA. The positive area was that to the right of the intersection of the two curves (42).
cells from three melanoma patients were compared with those of similar cells isolated from three normal subjects. As shown in Fig. 3a, the addition of CD25⁺CD69⁻ regulatory T cells to anti-CD3-stimulated PBLs resulted in a more marked suppression of lymphocyte proliferation on a per-cell basis than did the addition of CD25⁺CD69⁻ regulatory T cells isolated from normal subjects. The suppressive effect was partially inhibited by the MAb against CTLA-4 (Fig. 3b).

Expression of H- and L-Ferritin in Plasma of Melanoma Patients. It has been suggested that assay of H-Ferritin may detect abnormal levels of ferritin that may not be evident in assays against L-Ferritin (5). Therefore in the present study, an ELISA was developed using a polyclonal rabbit anti-placenta ferritin capture antibody (which binds both H- and L-Ferritin) combined with MAbs RH02 and LF03, which are specific for H- and L-Ferritin, respectively. Plasma from blood collected in EDTA was used for the assays to avoid the release of ferritin from red cells in the blood (43).

A representative study on plasma collected from 30 melanoma patients and 19 normal subjects (described in Tables 1 and 2, respectively) is shown in Fig. 4. There was an ~2-fold increase in the expression of H-Ferritin in plasma from melanoma patients compared with the normal subjects ($P = 0.0002$, by paired $t$ test; Fig. 4a). However there was no significant
difference in L-Ferritin expression in the plasma from melanoma patients and normal subjects (P = 0.7851; Fig. 4b). The ratio of H-Ferritin:L-Ferritin expressed in the plasma samples was calculated by dividing the total expression of H-Ferritin by the total expression of L-Ferritin. As shown in Fig. 4c, there was a significant difference in the H:L ratio between melanoma patients and normal subjects (P < 0.0001).

The expression of H-Ferritin or L-Ferritin or the H:L ratio in relation to clinical evidence or the stage of disease is also shown in Fig. 4. No significant difference was detected between the expressions of H-Ferritin (Fig. 4a), L-Ferritin (Fig. 4b), or the H:L ratio (Fig. 4c) among melanoma patients with and without clinical evidence of disease (P = 0.339, P = 0.951, and P = 0.100 respectively, by paired t test).

These was also no significant difference between stage of disease (using the American Joint Commission on Cancer and the International Union against Cancer Classification) and expression of H-Ferritin (stage II/III, P = 0.542; stage II/IV, P = 0.193; stage III/IV, P = 0.836), L-Ferritin (stage II/III, P = 0.646; stage II/IV, P = 0.512; stage III/IV, P = 0.913) or the H:L ratio (stage II/III, P = 0.421; stage II/IV, P = 0.165; stage III/IV, P = 0.470).

Relation of H-Ferritin in Plasma to Regulatory T Cells in Blood of Patients with Melanoma. Regression analysis was carried out to determine whether there was a correlation between the numbers of CD4⁺CD25⁺CD69⁻ regulatory T cells and expression of H- and L-Ferritin in melanoma patients or normal subjects (Fig. 5). As shown in Fig. 5, a and b, there was an inverse correlation between the level of CD4⁺CD25⁺CD69⁻ regulatory T cells and the levels of L-Ferritin, but no correlation with the level of H-Ferritin (P = 0.416, r = 0.025).
A positive correlation was also seen between regulatory T cells and the ratio of H-Ferritin:L-Ferritin (Fig. 4c; \( P = 0.002, r = 0.307 \)). L-Ferritin binds to H-Ferritin; therefore, the ratio of H-Ferritin:L-Ferritin is a reflection of the amount of free H-Ferritin. The latter results are, thus, consistent with our previous studies in vitro showing induction of regulatory T cells by H-Ferritin (22).

**Sequential Studies on CD4\(^+\) CD25\(^+\) CD69\(^-\) Regulatory T Cells and H- and L-Ferritin Expression in Melanoma Patients.** Additional studies were undertaken to determine whether there was a correlation between the ratio of H-Ferritin: L-Ferritin and regulatory T cells in patients during the course of their disease. H and L-Ferritin expression and numbers of CD4\(^+\) CD25\(^+\) CD69\(^-\) regulatory T cells were assayed in blood samples collected from three AJCC stage-III patients (patients DA, PV, and AM) and one stage-IIb patient (BK) over a 10–12-week period.

As shown in Fig. 6, the ratio of H-Ferritin:L-Ferritin changed in parallel with the percentage of CD4\(^+\) CD25\(^+\) CD69\(^-\) regulatory T cells in the melanoma patients. There was, however, no consistent change in these parameters during the period of the study. The expression of H-Ferritin/L-Ferritin and the percentage of CD4\(^+\) CD25\(^+\) CD69\(^-\) regulatory T cells decreased in patient DA (Fig. 5a); conversely, in patient PV, there was a small increase in the expression of H-Ferritin/L-Ferritin and the percentage of CD4\(^+\) CD25\(^+\) CD69\(^-\) regulatory T cells (Fig. 5b). In patient BK or AM (Fig. 5, c and d, respectively), no change in expression of H-Ferritin or in the number of CD4\(^+\) CD25\(^+\) CD69\(^-\) regulatory T cells was observed.

**DISCUSSION**

We have shown previously that H-Ferritin suppresses the response of blood lymphocytes to anti-CD3 in vitro by activating CD4 regulatory T cells in blood (22). The present studies extend these findings by showing that levels of H-Ferritin and regulatory T cells were increased in the circulation of patients with melanoma. Moreover, there was a correlation between the two findings, suggesting that the elevated levels of H-Ferritin may be causally related to the elevated levels of regulatory T cells.

Elevated levels of ferritin have been reported in patients...
with renal cell carcinoma (20), neuroblastoma (1, 18), and melanoma (19). In the latter study, elevated levels of ferritin was found in nine patients with disseminated melanoma but not in patients with resected primary or regional lymph node metastases. Most of the assays in these studies were based on antibodies raised against the whole ferritin molecule, most commonly from liver, which is rich in L- rather than H-Ferritin (4). It is, therefore, possible that elevated levels of H-Ferritin may not have been detected in these studies. This would explain why, in the present study, elevated levels of H-Ferritin were detected in melanoma patients in all stages of the disease and not just in patients with advanced progressive disease (19). Another critical factor in such assays is the avoidance of hemolysis during blood collection, which would result in falsely high ferritin levels. This was avoided in the present study by EDTA anticoagulation of the samples. The present studies are consistent with those of Hazard and Drysdale (5) who demonstrated increased levels of H-Ferritin relative to L-Ferritin in plasma samples from patients with breast, ovarian, pancreatic, and stomach carcinomas.

The source of the elevated levels of H-Ferritin remains of much interest. We have previously reported that melanoma supernatants contained elevated levels of H-Ferritin, and we assumed that H-Ferritin in the circulation of patients may be from their melanoma (21). If that were the case, it might be expected that there would be a correlation with the clinical stage of the disease and, particularly, the bulk of the tumor in the patient. This was not the case; and it is, therefore, possible that the source was normal body tissue. Most of the latter, however, is rich in L-Ferritin, which was not elevated in the circulation of melanoma patients. Non-specific activation of the reticuloendothelial system has been reported to result in abnormal iron metabolism (44). It is not clear whether this is associated with elevated H-Ferritin levels, but, if so, this may explain the present findings. Additional studies are needed on this aspect. A lack of correlation between regulatory T cell levels and disease stage or tumor bulk was reported in studies on patients with lung (45) and renal carcinoma (20).

In view of the association in vitro between H-Ferritin and the induction of regulatory T cells (22), it was of much interest to find that a similar correlation existed in patients with melanoma. The association between H-Ferritin and regulatory T cells was also supported by sequential studies on four patients showing parallel changes in both assays over time. The identification of regulatory T cells in patients by MAbs against CD4 and CD25 as reported by others (24, 46–48) was considered potentially misleading because normal CD4+ T cells may express CD25 when activated by antigen. To avoid this possibility, the activation marker CD69 was used to identify activated CD4 T cells and to exclude them from the analysis using three-color flow cytometry. A small proportion of regulatory T cells may also express this marker; therefore, the results in this study represent a minimal estimate of the number of regulatory T cells in the patients. Even so, it was apparent that up to 30% of CD4+ T cells in melanoma patients were regulatory T cells. When tested ex vivo, the latter cells appeared to suppress responses of lymphocytes stimulated by anti-CD3 to a greater degree than regulatory T cells from normal subjects, indicating that both the number and their function were elevated in melanoma patients.

The cause of the increased numbers of regulatory T cells in
