Abstract

Purpose: As genome-scale technologies begin to unravel the complexity of the equivalent tumors in adults, we can attempt detailed characterization of high-grade gliomas in children, that have until recently been lacking. Toward this end, we sought to validate and extend investigations of the differences between pediatric and adult tumors.

Experimental Design: We carried out copy number profiling by array comparative genomic hybridization using a 32K bacterial artificial chromosome platform on 63 formalin-fixed paraffin-embedded cases of high-grade glioma arising in children and young people (<23 years).

Results: The genomic profiles of these tumors could be subclassified into four categories: those with stable genomes, which were associated with a better prognosis; those with aneuploid and those with highly rearranged genomes; and those with an amplifier genotype, which had a significantly worse clinical outcome. Independent of this was a clear segregation of cases with 1q gain (more common in children) from those with concurrent 7 gain/10q loss (a defining feature of adults). Detailed mapping of all the amplification and deletion events revealed numerous low-frequency amplifications, including IGFR1, PDGFRB, PIK3CA, CDK6, CCND1, and CCNE1, and novel homozygous deletions encompassing unknown genes, including those at 5q35, 10q25, and 22q13. Despite this, aberrations targeting the “core signaling pathways” in adult glioblastomas are significantly underrepresented in the pediatric setting.

Conclusions: These data highlight that although there are overlaps in the genomic events driving gliogenesis of all ages, the pediatric disease harbors a distinct spectrum of copy number aberrations compared with adults. Clin Cancer Res; 16(13); 3368–77. ©2010 AACR.

The use of genome-scale profiling techniques to identify the key genetic aberrations underlying various tumor types has led to fundamental discoveries about the drivers of oncogenesis, and provides the rationale for specific targeted therapies in these lesions. Until recently, the application of such studies to the fields of high-grade glioma specifically, and childhood tumors in general, have lagged behind the adult epithelial cancers. This is now rapidly changing, with large screens of adult glioblastoma through collaborative networks (1) or single institutions (2) joining an increasing number of smaller independent studies (3–7) in comprehensively mapping the glioblastoma genome.

There are also beginning to emerge genomic studies specifically addressing childhood cancers, and there is mounting evidence that the pediatric high-grade glioma genome has certain key differences with that of histologically similar adult tumors. An early study using metaphase comparative genomic hybridization (CGH; ref. 8) highlighted distinct chromosomal changes in 23 childhood cases, a result borne out in a later 10K single nucleotide polymorphism (SNP) array study of a further 14 high-grade tumors (9), and more recent studies of 18 pediatric glioblastoma on Illumina 100K arrays (10), and 20 high-grade tumors using molecular inversion probes (11). Most recently, we participated in a collaborative effort to carry out molecular profiling of 78 pediatric high-grade gliomas by Affymetrix 500K SNP and U133 Plus2.0 expression arrays (12). From all these studies, it seems clear that although there are many large-scale chromosomal and...
**Translational Relevance**

Pediatric high-grade gliomas represent clinically devastating and biologically understudied tumors of the central nervous system. Little is known about the key genomic alterations that arise in childhood cases, nor of the specific differences between these and the adult disease. We present the copy number profiling of a large series of these rare tumors, and identify numerous low-frequency events previously unreported in pediatric high-grade glioma, including the potential therapeutic target \( \text{IGF}1R \). Tumors could be classified into distinct genomic subtypes, with marked differences in clinical outcome, and an idealized \( \text{PDGFRA}^{\text{amp.}} \), 1q+, 16q-genotype was considerably enriched in pediatric cases, in contrast to the \( \text{EGFR}^{\text{amp.}}, \text{7+,} \), 10q- cases more commonly associated with adults. We further highlight the importance of platelet-derived growth factor (PDGF) signaling in this context, through the most commonly observed genomic amplification of \( \text{PDGFRA} \), as well as a unique amplification of \( \text{PDGFRB} \), providing strong rationale for clinically targeting this pathway in children with this disease.

Although these studies are beginning to unravel the key features of the pediatric high-grade glioma genome, the total number of cases studied remains considerably smaller than for adult tumors. This is of particular importance given the lower frequency of the majority of genetic aberrations detected in childhood cases. Validating these low-frequency events in independent cohorts as being recurrent abnormalities, as well as the likely identification of novel isolated copy number changes will aid our understanding of the key pathways underlying the diversity of high-grade gliomas in children. To this end we carried out an array CGH study of 63 cases of pediatric high-grade glioma from formalin-fixed, paraffin-embedded (FFPE) archival pathology specimens on a 32K tiling-path bacterial artificial chromosome (BAC) platform.

**Materials and Methods**

**Samples and DNA extraction**

High-grade glioma samples from 63 patients (<23 years old) treated at the Royal Marsden Hospital (RMH), Sutton, and the Newcastle Royal Infirmary, United Kingdom, were obtained after approval by local and multicenter ethical review committees. The collection consisted of 37 glioblastoma multiforme, 14 anaplastic astrocytomas, 4 anaplastic oligodendrogliomas, 4 diffuse intrinsic (brain stem) gliomas, 2 astroblastoma, 1 oligoastrocytoma, and 1 gliosarcoma. All cases were archival FFPE tissues. The presence of tumor tissue in these samples and the tumor type were verified on a H&E-stained section independently by two neuropathologists (DWE and SA-S). Nine of the cases were previously profiled from a frozen tumor specimen in the collaborative SNP study (12). DNA was extracted using the DNeasy Tissue Kit (Qiagen) according to the manufacturer’s protocol and quantitated on a NanoDrop spectrophotometer (Thermo Scientific).

**Array CGH**

All raw and processed data have been deposited in Array Express (http://www.ebi.ac.uk/microarray-as/ae/; E-TABM-857). The array CGH platform used in this study was constructed at the Breakthrough Breast Cancer Research Centre and comprises 31,619 overlapping BAC probes covering the human genome at an approximate resolution of 50 kb (A-MEXP-1734). Hybridizations were carried out as previously described (15) and slides were scanned using an Axon 4000B scanner (Axon Instruments) with images analyzed using Genepix Pro 4.1 software (Axon Instruments). The median localized background slide signal for each clone was subtracted and each clone Cy5/Cy3 ratio was normalized by local regression (loess) against fluorescence intensity and spatial location. Clones overlapping known copy number variants were removed for statistical and visualization purposes, but not for mapping of specific amplifications.
and deletions, which was done according to the March 2006 build of the human genome sequence (hg18).

**Data analysis**

All data transformation and statistical analysis were carried out in R 2.9.0 (http://www.r-project.org/) and BioConductor 2.4 (http://www.bioconductor.org/), making extensive use of modified versions of the package aCGH in particular (15). For identification of DNA copy number alterations, data were smoothed using a local polynomial adaptive weights procedure for regression problems with additive errors, with thresholds for assigning "gain" and "loss" set at 0.1 (3 × SD of control hybridizations). For visualization purposes, the processed log2 ratios were colored green (gain) or red (loss) after segmentation and copy number determination.

To assess the significance of the genomic alterations, we applied an algorithm similar to those previously described, namely, Genomic Identification of Significant Targets in Cancer (GISTIC; ref. 13) and Genome Topography Scanning (GTS; ref. 16), taking into account the frequency, amplitude, and focality of the observed amplifications (log2 ratio >1.0) and deletions (log2 ratio <−0.75). This was calculated as the product of the absolute log2 ratio, the number of chromosomes in each segment, and the frequency within the entire cohort, scaled to the absolute maximum for amplifications/deletions separately, and overplotted on the frequency histogram for gains and losses described above.

**Fluorescent in situ hybridization**

Fluorescent in situ hybridization (FISH) analysis was carried out on FFPE sections as previously described (17). Probes directed against MYCN (pool of clones RP11-1183P10, RP11-674F13 and RP11-754G14), PIK3CA (RP11-4B14, RP11-642A13, RP11-379M20), PDGFRα (RP11-819D11, RP11-58C6), SKP2 (RP11-749P08, CTD-2015I17, RP11-203H14, RP11-189B22), PDGFRB (RP11-211F05, RP11-21120), MYC (RP11-440N18, RP11-237F24, CTD-2034C18), CDK4 (RP11-66N19, RP11-277A02, RP11-672O16), MDM2 (RP11-611O02, RP13-618A08, CTD-2067J14), and IGF1R (CTD-2015I17, RP11-203H14, RP11-189B22) were labeled with Cy3 (GE Healthcare), whereas chromosome-specific control probes at loci of no copy number change were labeled with fluorescein (GE Healthcare). Hybridized preparations were counterstained with 4′, 6-diamidino-2-phenylindole in antifade (Vector Laboratories Inc.). Images were captured using a cooled charge-coupled device camera (Photometrics).

**Statistics**

All statistical tests were done in R2.9.0. Correlations between categorical values were done using the $\chi^2$ and Fisher’s exact tests. Correlations between continuous variables were done using Student’s t test or the Mann-Whitney U test. Cumulative survival probabilities were calculated using the Kaplan-Meier method on uniformly treated patients within our cohort from the same institution (RMH), with differences between survival rates analyzed with the log-rank test. Important prognostic information (including extent of resection, Karnofsky performance score) was not available for all cases in this retrospective study, so multivariate analysis could not be done. All tests were two-tailed, with a confidence interval of 95%. P values of <0.05 were considered statistically significant.

**Results**

**Distinct patterns of copy number change in the pediatric high-grade glioma genome**

Previously we utilized whole genome amplification strategies for array CGH studies of tumors extracted from FFPE specimens (18). In this study, however, we were able to utilize a cohort of samples for which sufficient material was available to avoid the previous approach. We were able to generate high-quality copy number profiles from an unselected series of 63 pediatric high-grade gliomas using 32K tiling-path BAC arrays from which the tumor cell purity could be verified as >90% without the need for additional steps.

We observed a mean number of large-scale (whole chromosome or chromosomal arms) gains and losses of 5.8 per sample (median, 4; range, 0-22), with more losses (mean, 3.5; median, 3; range, 0-14) than gains (mean, 2.3; median, 2; range, 0-11). There was a further mean of 1.8 focal amplifications/deletions per sample (median, 1; range, 0-11), again with a slightly increased number of deletions (mean, 1.0; median, 0; range, 0-8) compared with amplifications (mean, 0.8; median, 0; range, 0-4). The list of observed alterations is given for the full dataset in Supplementary Table S1.

We were able to subtype the samples into four groups based upon the pattern of their genomic profiles. First was a group of tumors that had a very stable genome, with fewer low-level, focal changes. This subtype comprised 13 of 63 (20.6%) cases, and included 8 tumors (12.7%) that harbored no detectable copy number alterations on our 32K BAC platform (Fig. 1A). The second type contained only large, single copy alterations involving whole chromosomes or chromosomal arms, resulting in aneuploidy in the absence of any high-level amplifications in 22 of 63 (34.9%) cases, the largest subgroup we observed (Fig. 1B). The third type harbored numerous, low-level, intrachromosomal breaks resulting in multiple gains and losses and a highly rearranged genome. This group was also defined for this purpose by exclusion of cases with bona fide amplicons, and comprised 11 of 63 (17.5%) of the cohort (Fig. 1C). Finally, we considered those tumors with single or multiple high-level (log2 ratio >1.0) amplifications, regardless of the genomic background, as belonging to the fourth, “amplifier” subtype. This group consisted of 17 of 63 (27.0%) of cases (Fig. 1D).

There were no significant correlations between genomic subtype and WHO grade or histology ($P > 0.05$, Fisher’s exact test), with glioblastomas, anaplastic astrocytomas,
and anaplastic oligodendrogliomas spread across all subtypes. Of note, there were no “stable” genomic cases among the series of five patients that were treated for a previous malignancy by cranio-spinal radiation (post-IR; Supplementary Table S1). There was also no association of copy number profiles with age at diagnosis ($P > 0.05$, Mann-Whitney $U$ test), although the amplifier group did not include any infant tumors (<3 years). However, when we investigated the overall survival of the patients treated at a single institution (RMH), we detected significant differences by retrospective univariate analysis in the clinical outcome of cases according to the genomic profile of the tumor. The stable genome cases showed a trend towards better prognosis when compared with all other cases ($P = 0.0755$, log-rank test), whereas the samples with an amplifier genome had a significantly shorter time to death.

Fig. 1. Pediatric high-grade gliomas comprise different subtypes of copy number profiles. Sample genome plots are given for stable (A), aneuploid (B), rearranged (C), and amplifier (D) genomes within our sample cohort. Log$_2$ ratios for each clone (Y-axis) are plotted according to chromosomal location (X-axis). Vertical lines, centromeres; green points, gains; red points, losses.

Fig. 2. Genomic subtypes of pediatric high-grade glioma have prognostic relevance. Kaplan-Meier plot for overall survival of pediatric high-grade gliomas treated at a single institution stratified according to genomic subtype. The stable genome cases showed a trend towards better prognosis when compared with all other cases ($P = 0.0755$, log-rank test), whereas the samples with an amplifier genome had a significantly shorter time to death ($P = 0.00214$, log-rank test).
The aneuploid and rearranged cases fell in between, and were representative of the survival characteristics of the cohort as a whole, suggesting that they may need to be considered together as falling between the extremes of the other two groups.

One of the defining features of pediatric high-grade glioma is the frequent gain of chromosome 1q (12 of 63, or 19.0%, versus 17 of 189, or 9.0%, of adult cases; ref. 1; \( P = 0.039 \), Fisher’s exact test) and loss of 16q (11 of 63, or 17.5%, versus 14 of 189, or 7.4%; \( P = 0.028 \), Fisher’s exact test); in contrast to adult glioblastoma cases, in which gains of chromosome 7 (12 of 63, or 19.0%, versus 140 of 189, or 74.1%; \( P < 0.0001 \), Fisher’s exact test) and losses of 10q (10 of 63, or 15.9%, versus 152 of 189, or 80.4%; \( P < 0.0001 \), Fisher’s exact test) predominate. In our FFPE cohort, we noticed a clear distinction of 1q gain cases from those with concurrent 7 gain/10q loss (7+/10q-, 8 of 63, or 12.7%), with only a single case harboring both abnormalities. Neither event was significantly associated with any clinicopathologic parameters, although there was a trend towards shorter survival in the 1q+ cases (\( P = 0.0865 \), log-rank test).

Neither abnormality was seen in any infant cases.

**Mapping of focal amplifications and deletions to known oncogenes and novel loci**

As we had with large-scale alterations, we observed numerous focal amplifications and deletions. In summary, we identified 47 unique amplification and 32 unique deletions. All these events are detailed in full in Supplementary Table S2 (amplifications) and Supplementary Table S3 (deletions).

The most common amplicon was at 4q12 (10 of 63, or 15.9%), and deletion at 9p21 (10 of 63, or 15.9%, consisting of 8 homozygous, 2 hemizygous). Mapping the SRO in these cases narrowed these regions specifically to PDGFRA and CDKN2A, respectively, confirming the initial observations that these are by far the most common amplifications/deletions in pediatric high-grade glioma (12). Other common events included amplification of MYCN at 2p24 (3 of 63, or 4.7%) or MYC at 8q24 (2 of 63, or 3.2%), together giving a frequency of 7.9% (5 of 63) of cases with genomic MYC family dysregulation; and 3 of 63 (4.7%) EGFR amplification at 7p12 – a lower frequency than observed in our recent chromogenic in situ hybridization study of a larger cohort of which this series is a subset, reflecting the focal nature of the amplification event in a small number of tumors identified by molecular pathology (19).

For the remaining aberrations, we highlighted the SROs where they were found to be recurrent. However, as most were present only in a single case, and we were unable to narrow down gained/lost regions, the result was that we identified a total of 1,026 amplified and 1,243 deleted genes across our series. To facilitate the identification of key oncogenic events in pediatric high-grade glioma, we sought to assign significance to the genomic aberrations we observed. Inspired by algorithms such as GISTIC (13) and GTS (16), we developed a simple measure based upon three key features of our data for each clone on the array: (a) frequency of high-level amplification/homozygous deletion, (b) absolute magnitude of the change, and (c) focality of the segmented copy number change. This amplitude/focality measure was then scaled to the maximum and minimum for amplifications/deletions, respectively, and plotted over the frequency of low-level gains and losses on the same histogram (Fig. 3).

As well as PDGFRA (the highest scoring gene) and CDKN2A, this analysis highlighted the importance of several known oncogenes, amplified at low frequency in our series, but at high magnitude, and in a focally restricted...
manner. These included PIK3CA (3q26), CDK6 (7q21), and CDK4 (12q14), the first two previously reported in adult glioblastoma, but not in pediatric cases, and present here in a single case. We also identified amplifications of two additional receptor tyrosine kinases: IGF1R at 15q26 (Fig. 4A) and PDGFRB at 5q33 (Fig. 4B). Such an approach further highlighted the potential significance of known deletions targeting PARK2 at 6q6 and MGMT, PTPRE, and others at 10q26, as well as unique events for which the candidate gene is unknown at 10q25 (Fig. 4C) and 11q14 (Fig. 4D).

We were able to validate nine of these lower-frequency amplification events by carrying out FISH on our FFPE sections using specific probes against MYCN, PIK3CA, PDGFRα, SKP2, PDGFRβ, MYC, CDK4, MDM2, and IGF1R (Fig. 5).

Glioblastoma core signaling pathways are not commonly activated by copy number changes in pediatric patients

One of the most important findings from recent large-scale genomic profiling studies of adult glioblastoma was the identification of three core signaling pathways that were abrogated by amplification, deletion, and/or mutations of key genes in the vast majority of cases. Considering only the copy number data from these studies, 59%, 70%, and 66% of cases were found to have at least one genetic event targeting the receptor tyrosine kinase/phosphoinositide 3-kinase (RTK/PI3K), p53, or RB pathways, respectively (1, 2).

We mapped the copy number changes in our pediatric cases to the same pathways, which included many of the genes described above, as well as others described in adult...
glioblastoma, including MET, KRAS, and AKT2 (RTK/PI3K), MDM2 (p53), and CCND2 (RB). Despite this, we observed a significantly lower frequency of pathway dysregulation compared with that reported in adults: 16 of 63 (25%) RTK/PI3K, 12 of 63 (19%) p53, and 14 of 63 (22%) RB (all \( P < 0.0001 \), Fisher's exact test; Fig. 6). Even after removing the stable genome subtype from this analysis, it is apparent that pediatric tumors show targeting of these core pathways by copy number alterations in less than half as many instances than in adults.

To explore whether other canonical pathways may be activated by this mechanism preferentially in childhood tumors, we mapped amplified/deleted genes in those tumors without core pathway targeting via GenMAPP. Although there were isolated cases with clear genomic events linked to activation of the Sonic Hedgehog (GLI2 amplification, HHIP deletion) and Notch (DLL3 amplification, DLK1 deletion) pathway activation, there was no consistently targeted pathway in these cases, nor was there specific enrichment of any additional pathway across the entire cohort.

**Discussion**

We were previously part of a collaborative study setting out to comprehensively map the copy number alterations present in the pediatric high-grade glioma genome, in which we used Affymetrix 500K SNP arrays on a series of 78 cases available as frozen tumor samples (12). Those data revealed an overlapping, but distinct, underlying molecular genetics of the childhood disease when compared with recent large-scale genomic analyses of adult high-grade glioma (1, 2). Along with the common amplification/deletion targets of PDGFRA and CDKN2A/B, there were numerous low-frequency events targeting both well-recognized
oncogenes and novel loci. The present study had three purposes: (a) to validate the high-frequency events in an independent set of samples, analyzed on an independent microarray platform; (b) to extend the sample set to provide evidence of recurrence of the low-frequency events previously reported; and (c) to identify novel low-frequency events, which by their nature may have been missed in the earlier study.

The most frequent focal events were PDGFRA amplification and CDKN2A/B deletion, and the most common large-scale gains and losses included chromosomes 1q and 16q, respectively. The PDGFRA^{amp}, 1q+, 16q- events were significantly more common in the childhood setting (10, 11, 20), although it is important to note that they are present in a proportion of adult tumors. Similarly, we observed a group of tumors in our cohort containing aberrations more commonly associated with the adult disease, namely EGFR^{amp}, 7+, 10q-, albeit at significantly reduced frequencies. That they tended towards exclusivity suggests they represent archetypes for different ends of the spectrum of the disease.

One of the most intriguing differences observed in the pediatric setting was the presence of a proportion of cases of high-grade tumors with very few, or even no detectable copy number alterations. This was true on both BAC...
downregulation may be active, as two cases of homozygous deletion, other mechanisms of and differentiation (28). Although we have now observed through specific binding interactions with the receptor number of microRNAs, as well as the gene lesions include those at 14q32, encompassing a large known oncogenes within the core signaling pathways described in adult glioblastoma, such as CDK6 (10), MET, and CCND2, as well as novel targets. These include ID2 at 2p25, previously found in association with the MYCN amplicon at 2p24, possibly part of a single event, identified here as an independent target in its own right. ID2 is a helix-loop-helix transcription factor that has previously been shown to be widely expressed in astrocytic tumors (21, 22), and may play a role in negatively regulating cell differentiation and promoting cell survival (23, 24). Another amplicon at 17q22 was also confirmed in the FFPE series, with a SRO analysis identifying RNF43 as the most likely target. RNF43 is a ubiquitin ligase that promotes cell growth and is upregulated in colon cancer (25, 26), but has not previously been implicated in gliomagenesis.

Homozygous deletions now apparent as recurrent lesions include those at 14q32, encompassing a large number of microRNAs, as well as the gene DLK1. DLK1 is a δ-like homolog that acts to inhibit Notch signaling through specific binding interactions with the receptor (27), and may play diverse roles in cellular transformation and differentiation (28). Although we have now observed two cases of homozygous deletion, other mechanisms of downregulation may be active, as DLK1 is present at an imprinted locus, with increased methylation upstream of the GTL2 leading to reduced expression in other tumor types (29). Other deletions may have a more complicated role in gliomagenesis such as those on chromosome 16q. The SNP study identified a large deletion in a single tumor that is present as two separate events at 16q12 and 16q21 in two independent cases here, targeting numerous candidates including clusters of Iroquois homeobox genes, metallothioneins, and coiled-coil domain containing genes. By contrast, a homozygous deletion observed in the present study overlaps two independent loci previously reported at 11q14 to target a single microRNA, hsa-mir-708, and a single gene, ODZ4. Although little seems known about mir-708, the odd Oz/ten-m homolog 4 is expressed in the developing and adult central nervous system, and seems to act as an important transcriptional regulator associated with neurodevelopment (30, 31).

Finally, we were also able to identify several novel amplifications and deletions, the significance of many of which is not yet clear. There were some genes identified that were also present in adult glioblastoma studies which had not previously been reported in pediatric high-grade glioma, such as AKT2, CCNE1, GLI2, MDM2, PARK2, and PIK3CA. There were other previously unreported genes that may be associated with specific glioblastoma-related signaling pathways such as AKTIP (16q12), an Akt-interacting protein that acts as an activator of the PI3K pathway (32), and PIK3C3 (18q12), also known as Vps34, a member of the PI3K family associated with autophagy (33). There were numerous others with potential functional relevance unknown.

We also noted rare amplifications at receptor tyrosine kinases considered less likely to be driven by copy number gain. Firstly was a very high level gain of IGF1R at 15q26 (11). Insulin-like growth factor (IGF) signaling has previously been implicated in gliomagenesis, primarily on the basis of high levels of the ligand IGF2 in glioblastoma specimens (34). The growth-promoting effects of IGF2 that were shown were mediated via IGF1R and the PI3K regulatory subunit PIK3R3. Of particular relevance to the childhood setting was the observation of a mutual exclusivity between IGF2-associated tumors and EGFR-driven cases, suggesting that the IGF pathway may play a prominent role in pediatric tumors, possibly in concert with PDGF receptor (PDGFR)-related signaling.

Secondly was an amplicon at 5q33 which included PDGFRB (and another receptor tyrosine kinase CSF1R). Given the clear importance of PDGFR signaling on pediatric high-grade gliomas, it is perhaps unsurprising that there may be multiple mechanisms active in driving tumorigenesis through a common pathway. To this end, we also observed recurrent amplification of the ligand PDGFB (22q13) in the previous SNP study (12), and here further observed focal copy number gain at 7p22 encompassing PDGFA. That these unique genomic events have thus far been found to be restricted to pediatric tumors adds further evidence to a distinct underlying genetics driving archetypal high-grade gliomas in children, one that is largely PDGF-driven, and forms a discrete pole within the diversity of glioma biology. Understanding the most appropriate ways of efficaciously targeting these pathways in the most appropriate patient populations will hopefully overcome the disappointing early-phase clinical trials observed thus far with PDGFR inhibitors.
