Abstract

Purpose: Postactivation barriers to oncology clinical trial accruals are well documented; however, potential barriers prior to trial opening are not. We investigate one such barrier: trial development time.

Experimental Design: National Cancer Institute Cancer Therapy Evaluation Program (CTEP)-sponsored trials for all therapeutic, nonpediatric phase I, I/II, II, and III studies activated between 2000 and 2004 were investigated for an 8-year period (n = 419). Successful trials were those achieving 100% of minimum accrual goal. Time to open a study was the calendar time from initial CTEP submission to trial activation. Multivariate logistic regression analysis was used to calculate unadjusted and adjusted odds ratios (OR), controlling for study phase and size of expected accruals.

Results: Among the CTEP-approved oncology trials, 37.9% (n = 221) failed to attain the minimum accrual goals, with 70.8% (n = 14) of phase III trials resulting in poor accrual. A total of 16,474 patients (42.5% of accruals) accrued to those studies were unable to achieve the projected minimum accrual goal. Trials requiring less than 12 months of development were significantly more likely to achieve accrual goals (OR, 2.15; 95% confidence interval, 1.29-3.57, P = 0.003) than trials with the median development times of 12 to 18 months. Trials requiring a development time of greater than 24 months were significantly less likely to achieve accrual goals (OR, 0.40; 95% confidence interval, 0.20-0.78; P = 0.011) than trials with the median development time.

Conclusions: A large percentage of oncology clinical trials do not achieve minimum projected accruals. Trial development time appears to be one important predictor of the likelihood of successfully achieving the minimum accrual goals. Clin Cancer Res; 16(22): 5557–63. ©2010 AACR.

In the United States, it is estimated that 1.4 million individuals will be diagnosed with cancer, and over half a million will die each year. Advances in therapeutic treatments have improved the 5-year survival rates over the past four decades (1), yet cancer continues to be the second leading cause of death in Americans, resulting in more deaths than the next five causes combined (2). New and innovative therapeutic approaches to improve the standard of care for cancer patients must be developed and then confirmed through a series of clinical trial phases to ensure both efficacy and safety. Phase I to III trials require sufficient patient enrollment so that not only can the efficacy of the therapeutic agent(s) under investigation be tested with a proper degree of statistical certainty, but also to maximize the generalizability of the findings to the intended patient population. Unfortunately, with only 2% to 7% of the adult cancer population participating in clinical trials, obtaining sufficient accrual is a known barrier to successful completion of clinical trials (3, 4). Furthermore, it has been shown that the lack of appropriate trials represents a significant barrier to accruing oncology patients (5). Hence, there should be a sense of urgency to develop properly safeguarded oncology trials such that treatments discovered at the bench can be translated effectively and rapidly into improved standard of care.

Understanding the reasons behind low-accruing clinical trials is important. However, most of the efforts to reduce barriers to patient accruals have been concentrated on postactivation efforts, that is, after a trial is open for patient enrollment or accrual (6, 7). It is our contention that there are factors involved during trial development that significantly affect accrual performance. We postulate that the calendar time required to transit from letter of intent (LOI) or concept through protocol development to final trial activation is inversely related to the attainment of the accrual goal. Research has shown that the time to develop a phase III oncology trial...
requires nearly 26 months with intricate collaboration among a diverse set of organizations (8–10). Although there are any number of other causes that may be attributed to low accruing clinical trials, development time has been shown to be a well-established and critical factor in the success of a new product across a host of other applications (11).

To investigate the effect of trial development time on patient accruals to oncology trials, a retrospective evaluation was conducted on trials sponsored by the National Cancer Institute (NCI) Cancer Therapy Evaluation Program (CTEP). CTEP evaluates approximately 900 out of the 1,500 NCI-sponsored studies annually (12). All trials evaluated by CTEP are supported by NCI grants and cooperative agreements awarded to scientific institutions and individuals and are conducted by faculty members and practitioners at those institutions that initiated the trial idea. Trials that request CTEP support must be submitted for review once the concept is formulated. Once the concept or letter of intent is approved for development into a formal submission to CTEP as a trial idea. Trials that request CTEP support must be submitted for review once the concept is formulated. Once the concept or letter of intent is approved for development into a completed clinical trial, multiple and parallel tasks including protocol writing, regulatory, scientific and ethics reviews, and financial negotiations take place (8). It is only when all these tasks are completed synchronously is the development of a clinical trial complete. It is this development time and intricate coordination among the many stakeholders that we are interested in investigating. This article uncovers the critical, yet often overlooked, barrier of lengthy trial development time as a major factor negatively correlated with accrual performance in phases I to III CTEP-supported oncology trials.

Translational Relevance

The development of clinical trials has been shown to be a long and arduous process. Furthermore, obtaining adequate accruals to oncology clinical trials is a major and persistent problem. The present study uncovers the relationship of long development times on accrual performance. The implications of the findings highlight the importance of reducing all unnecessary delays; overcoming barriers to development time have implications to improving accruals to trials. The field of oncology evolves quickly, rendering original research questions obsolete if not implemented in a timely manner. Therefore, continued efforts to uncover additional barriers to development time are a critical component to translating scientific knowledge to improved therapeutic options.

Materials and Methods

All therapeutic, nonpediatric, phase I, I/II, II, and III oncology trials evaluated by CTEP opened to patient accrual between June 1, 2000 and December 31, 2004 in the United States with complete tracking information for development time were eligible. Evaluation of accrual performance was conducted as of December 31, 2008—allowing for trials to be open to accrual for a minimum of 4 years. Data were supplied by the CTEP-Protocol and Information Office, which maintains a tracking database of trial activities from concept submission to trial activation. Trials originated from multiple sources including NCI’s Clinical Trials Cooperative Group Program, Comprehensive Cancer Centers, Cancer Centers, and NCI-sponsored Consortiums.

The independent variable, development time, was the difference in calendar days between the date of initial CTEP receipt of letter of intent or concept and the date the trial was opened for accrual. For simplicity, calendar days were converted into months by dividing the total days by 30.33. It is important to note that this definition of development time does not include the days required to prepare the trial idea into a formal submission to CTEP as the consistency of the data is variable dependent on the institution where the trial was derived. Previous studies of phase III trials have shown that this initial time could consume between 1 and 10 calendar months (10).

The dependent variable, accrual-to-goal percentage, was calculated using projected minimum accrual goal and actual trial accrual at trial closure. This provides a liberal estimate of the attainment of the accrual goal because it defines the minimum trial sample size needed to achieve the desired scientific end point. The minimum projected accrual goal for each trial is defined within the study design of each trial and is highly dependent on the phase. Specifically, phase I minimum projected accrual goals assumes that the dose-limiting toxicity is observed at the first dose level; phase I/II trials establish minimum projected accruals based on the phase I accrual and updates the minimum accrual when the trial transitions to a phase II trial; Minimum accrual goals for phase II and III trials are based on the number of accruals required to complete the first stage of the study design. It is noted that the minimum projected accrual goals for phase I, I/II, and II trials are most likely underestimates as these are the absolute minimums necessary to complete the trial and does not account for the necessary accrual to achieve the intended trial end points.

Final patient accrual was obtained from the CTEP-Protocol and Information Office database, with input from the Clinical Data Update System and the Clinical Trials Monitoring Service. Trials that were withdrawn for any reason were excluded (n = 1).

Accrual-to-goal percentage was computed by dividing the actual trial accrual at trial closure by the projected minimum trial accrual goal. Attainment of the accrual goal was defined as a trial that achieved ≥100% of its projected minimum accrual at trial closure for studies that were completely closed to accrual. Trials were opened for patient accrual at least 3 years before the evaluation of the trial for accrual performance. Attainment of the accrual goal was more liberally defined for those studies that remained opened to accrual at the time of trial sampling as those that achieve ≥75% of its projected minimum accrual to account for the possibility of those studies to achieve the intended accrual goal.
Clinical Trial Development as a Predictor of Accrual Performance

Statistical analysis
Continuous variables were summarized by calculating medians and interquartile ranges (IQR). A maximum two-tailed \( \alpha \) of 0.05 was maintained for determining statistical significance. Comparisons among trial types (i.e., phases I, I/II, II, and III) were conducted using the Kruskal-Wallis test. Post hoc comparisons of statistically significant overall tests used Mann-Whitney tests with a Bonferroni-adjusted \( \alpha \) level of 0.008. Categorical and ordinal groups were summarized using univariate and cross-tabulated frequency distributions. Unadjusted odds ratios (OR) were obtained using bivariate logistic regression analysis. To account for the dramatic differences among the sizes of the trials (e.g., phase III tending to be larger than other types of trials, minimum accrual projections were included in multivariate logistic analyses to generate adjusted ORs, along with their respective 95% confidence intervals (CI). Statistical analyses were done in either SPSS (version 15.0, descriptive and logistic regression).

Results
A total of 419 CTEP-sponsored phase I, I/II, II, and III therapeutic, nonpediatric oncology trials that were initiated to patient enrollment within the study period were eligible (Fig. 1). Table 1 summarizes the development time and minimal accrual characteristics by phase of trial. Phase II trials accounted for the majority (45.8%, \( n = 192 \)); phase I trials composed 34.1% (\( n = 143 \)), followed by phase III (11.5%, \( n = 48 \)) and phase I/II (8.6%, \( n = 36 \)). Trials with incomplete development time data were excluded (\( n = 443 \)). Incomplete development timing data were observed for reasons including the timing metrics were not being captured in the electronic system (\( n = 72 \)), the concept submission date was not available (\( n = 354 \)), and the activation and concept dates were inconsistent (\( n = 17 \)). The largest exclusion criteria being attributed to the unavailability of the concept date was due to the fact that the clinical trial development process did not include CTEP collaboration during the concept/LOI process; thus, no record was available in the CTEP databases. There were no statistically significant differences observed in accrual achievement between included and excluded studies (\( P = 0.129 \)).

Overall median development time from initial CTEP submission to trial activation for all types of trials was 14.2 months (IQR, 11.3-18.5). Phase III trials had statistically longer development times than other types (\( P < 0.008 \)), with a median development time of 17.9 months (IQR, 14.2-23.8). None of the differences in development time between the other types of trials were statistically significant.

Median minimum projected accrual goal for all types of trials was 21 subjects (IQR, 15-38; Table 1). There were significant differences in projected minimum accrual goals between phase I trials compared with phase I/II, phase II, and phase III trials (\( P < 0.008 \)). Additionally, phase III trials had significantly greater projected minimum patient accruals when compared with trials of all other phases (\( P < 0.008 \)).

A total of 308 trials (73.5%) in the cohort were closed to accrual at the time of inspection. Those trials that remained open to patient enrollment as of January 31, 2007 (\( n = 111 \), 26.5%) had a median accrual period of 47 months (IQR, 41.4-59.0) with a minimum accrual period of 36.4 months. Phase III trials were the predominant trials that remained open (\( n = 19 \), 39.6%) followed by phase I (\( n = 45 \), 31.5%), phase II (\( n = 41 \), 21.4%), and phase I/II (\( n = 6 \), 16.7%) trials. There was no statistical difference observed when comparing the attainment of accrual goal across trials that were closed to accrual and those that remained open (\( P = 0.476 \)).

As shown in Table 1, 37.9% (\( n = 221 \)) of all trials did not attain the accrual goal. However, performance of the phase III trials was statistically significantly lower than that of the other types of trials, with 70.8% (\( n = 34 \)) failing to achieve this standard of performance (\( P < 0.001 \)). Particularly problematic in phase III trials, a large number of trials (\( n = 30 \), 49.2%) failed to achieve \( \geq 30\% \) of their respective projected minimum accrual goals (Fig. 2).

A total of 38,724 individuals accrued to the oncology trials in the sample. The majority were enrolled in phase III trials (\( n = 26,999 \), 69.7%), followed by phase II (\( n = 6,560 \), 16.9%), phase I (\( n = 3,961 \), 10.2%), and phase I/II (\( n = 1,204 \), 3.1%). When comparing the proportion of total patients enrolled on trials to patients enrolled on trials that met their projected minimum accrual, it was found that a total of 16,474 participants (42.5%, min = 16.3% phase II, max = 53.8% phase III) were enrolled on clinical trials that closed with underperforming final accruals (Fig. 3).
For ease of interpretation, development time was collapsed into 6-month time intervals beginning after 12 months of accrual. Comparisons of the likelihood of achieving the accrual goal were conducted based on the referent category of 12 to 18 months, which was identified by the median development time of the entire sample of 14.2 months. Figure 4 summarizes the likelihood of achieving minimum accrual goals as the development time varied from the overall median development time.

Relative to trials that fell within the overall median development time, trials consuming less than 12 months of development time from the time of CTEP concept submission were statistically significantly more likely to achieve the minimum accrual goals (OR, 2.02; 95% CI, 1.21-3.37; \( P = 0.007 \)). On the other hand, trials requiring 24 months or greater of development time were statistically significantly less likely to achieve projected minimum accrual goals than those trials that fell within the overall median development time (OR, 0.41; 95% CI, 0.21-0.81; \( P = 0.011 \)). Trials with development times between 18 and 24 months had a proportionally decreasing likelihood of achieving minimum accrual goals, but the OR was not statistically significant (Table 2).

Given the previously established differences in development time of trials of different phases, the likelihood values adjusted for phase of trial were also summarized. Additionally, raw projected minimum accrual numbers tended to be larger with phase III trials. Because these numbers provide a continuous (and thus more powerful) explanatory variable for whether or not accrual goals were met, the development time likelihood values adjusted for raw minimum accrual projections were also displayed. ORs adjusted for raw projected accrual numbers or adjusted for the effect of phase III trials resulted in similar findings when compared with the unadjusted values.

### Discussion

This study provides an in-depth analysis of the development time of CTEP-sponsored oncology clinical trials as it affects trial accrual performance during an 8-year period. The findings show that the time to bring forth an idea from concept to trial activation has a significant inverse relationship with accrual performance. The implications of identifying this negative correlation between development time and accrual performance are multiple. First, trials that result in lower than the intended accruals have a limited capacity in statistically supporting the intended scientific objectives necessary to add to the body of scientific knowledge. Although early phase trials including phase I and I/II trials may achieve the scientific end point prior to enrolling the

*Success and failure of a study is defined by the accrual performance of studies closed to accrual and studies that are opened to accrual at the time of sampling.

†Accrual period for studies opened to accrual reflects the time that the study was opened at the time of study sampling. Actual accrual periods may be longer than observed.
necessary accruals, similar findings of low accrual performance were observed across all trials regardless of phase. In particular, this research highlights the importance of low accrual performance for phase III trials, where adequate accruals are critical in statistically supporting the underlying scientific objective. Additionally, the scarce resource of patients is being underutilized if patients volunteer for a trial that never achieves its minimum accrual goal.\textsuperscript{5} Data from this research show that almost two out of every five CTEP-sponsored trials will fail to achieve sufficient accruals. For phase III trials, the rate increases to 7 failures out of every 10 trials conducted. Along the same lines, anywhere between 16\% (phase I and II) and 52\% (phase III) of participants were enrolled on a clinical trial that did not achieve minimum requirements in patient accruals. If we assume that minimum sample size goals were developed using statistical power analysis, failure to achieve such goals results in the limited ability to derive statistically valid conclusions, therefore resulting in a less significant advancement of science than originally intended.

Explanation for the observation in the inverse relationship between long clinical trial development time and poor accrual performance are numerous. The field of oncology clinical research evolves quickly, which may cause interest in the original research question to wane as development time is prolonged (6). Alternatively, long development times as well as poor accruals may be due to a lack of interest in the clinical trial from the origination of the idea. Should trials be allowed to begin enrolling patients if scientific interest has waned or the underlying scientific interest is not of importance? Regardless, pursuing clinical trials with a reduced likelihood of attaining the accrual goal limits the opportunity to conduct other clinical trials.

In an era of clinical research where material resources limit the number of trials that can be pursued, as well as the limited availability of individuals willing to participate in clinical trials, it is essential to identify potential causes of low accrual likelihood before allocating significant resources to develop such trials. The retrospective analyses of phase I, I/II, II, and III trials suggest that there are opportunities to improve the number of trials that attain the accrual goal. In particular, phase III clinical trial development times should be improved not only because of the potential importance of the findings of phase III trials on current standard of care, but also because such trials are the most resource-consuming in terms of time, effort, and patient accruals. In our analysis, we found that phase III trials both had the greatest amount of development time, the highest number of trials that did not achieve the accrual goals, and had the largest number of patients enrolled in studies that did not achieve necessary accruals. Clinical trial development time is complicated by the many facets of scientific study design within the constraints

\textsuperscript{5} We acknowledge that many clinical trials closed due to adverse events both related to the clinical trial itself as well as derived from other similar studies. Unfortunately, we do not have the rationale for study closing for the sample.
of regulatory, ethical, and operational requirements (13). Research delays during the development of a clinical trial can often be attributed to the improvement of overall scientific merit or to efforts meant to ensure the safety of potential participants. However, opportunities to improve development time arise when considering the number of non–value-added steps in the process flow, as well as the number of multiple, redundant, and/or overlapping steps involved in opening clinical trials (10, 14). Findings from this research indicate that any decisions beyond the scope of scientific relevancy or ethical issues that delay the deployment of clinical trials have negative repercussions on the likelihood of attaining the accrual goal.

Finally, why is longer development time of interest beyond its negative effects on the likelihood of attaining accrual goal? There are two other reasons: (a) patients will gain access to new therapies later than they otherwise would (if ever) and (b) longer development times create reduced innovation incentives as researchers concentrate on completing studies that have lower minimum patient accrual goals, which may result in fewer new therapies being developed. It is imperative that the systems and processes for clinical trial development be created to foster better and faster clinical trial development, with a minimum of administrative barriers. As noted in this study, a large number of trials (n = 419) were observed to have
incomplete development tracking data of studies. Utilizing predictors and metrics during the development stage of the clinical trial is critical not only as a method to track the progress of trials, but findings from this research suggest that it can be used to examine potential accrual performance prior to first enrollment. This poses additional question regarding the ethical implications of enrolling patients on studies with a diminished likelihood of achieving the ultimate accruals necessary to support the underlying scientific objective: have studies that have failed to complete the intended accrual breached an ethical contract with the participants, and moreover, should accrual and study results be disclosed to them?

A limitation of this analysis is that only the development time variable has been analyzed with regard to successful accrual. Although there is a host of other reasons for low accruals, this research shows that one previously overlooked but important barrier to accrual—development time—should be included in any investigation of low accrual causes. Continued research to uncover additional barriers within preactivation efforts is imperative to foster the rapid access of clinical trials to patients and to improve the likelihood of achieving the desired clinical trial objective.
