Translational Relevance:

We show for the first time the complex patterns of altered microRNA expression during the mucosa-adenoma-adenocarcinoma sequence in the colorectum. In addition, through bioinformatic analysis of the pathways targeted by the altered microRNAs, we highlight the importance of microRNAs as another mechanism for dysregulation of the \textit{Wnt} signaling pathway at the earliest step in tumorigenesis between non-neoplastic mucosa and low-grade dysplasia in adenomas. Because microRNAs are of interest as biomarkers and as therapeutic targets and agents, our findings identify specific microRNAs that are altered during the steps in colorectal tumor progression and may guide translation into clinical usage of microRNAs.
Abstract

Purpose: MicroRNAs are short non-coding RNAs that regulate gene expression and are over or underexpressed in most tumors, including colorectal adenocarcinoma. MicroRNAs are potential biomarkers and therapeutic targets and agents, but limited information on microRNAome alterations during progression in the well-known adenoma-adenocarcinoma sequence is available to guide their usage.

Experimental Design: We profiled 866 human microRNAs by microarray analysis in 69 matched specimens of microsatellite-stable adenocarcinomas, adjoining precursor adenomas including areas of high- and low-grade dysplasia, and non-neoplastic mucosa.

Results: We found 230 microRNAs that were significantly differentially expressed during progression, including 19 not reported previously. Altered microRNAs clustered into two major patterns of early (Type 1) and late (Type 2) differential expression. The largest number (n=108) was altered at the earliest step from mucosa to low-grade dysplasia (Subtype 1A) prior to major nuclear localization of beta-catenin, including 36 microRNAs that had persistent differential expression throughout the entire sequence to adenocarcinoma. Twenty microRNAs were intermittently altered (Subtype 1B), and six were transiently altered (Subtype 1C). By contrast, 33 microRNAs were altered late in high-grade dysplasia and adenocarcinoma (Subtype 2A), and 63 in adenocarcinoma only (Subtype 2B). Predicted targets in 12 molecular pathways were identified for highly altered microRNAs, including the Wnt signaling pathway leading to low-grade dysplasia. Beta-catenin expression correlated with downregulated microRNAs.

Conclusions: Our findings suggest that numerous microRNAs play roles in the sequence of molecular events, especially early events, resulting in colorectal adenocarcinoma. The temporal
patterns and complexity of microRNAome alterations during progression will influence the efficacy of microRNAs for clinical purposes.
Introduction

Colorectal cancer is the second most common cause of cancer deaths in the United States (1) and results from progressive genetic and epigenetic alterations in the epithelial cells of the large bowel mucosa (2-6). The adenoma with epithelial dysplasia is the usual benign precursor neoplasm in a well-known morphologic and temporal non-neoplastic mucosa-adenoma-adenocarcinoma (NM-A-AC) sequence that provides an opportunity to determine alterations that are important in progression during tumorigenesis.

Numerous alterations in oncogenes and tumor suppressor genes described in adenocarcinomas are also found in adenomas, including mutation of \textit{APC}, \textit{KRAS}, \textit{BRAF}, and \textit{P53} genes (2, 4). Tumors with chromosomal instability manifested by gains and losses of chromosomes and their parts are by far the most frequent molecular subtype of colorectal neoplasms and often have \textit{KRAS} or \textit{P53} mutation. By contrast, microsatellite instability is seen in a small subset of colorectal adenocarcinomas due to loss of function of the DNA nucleotide mismatch repair system usually caused by silencing of \textit{MLH1} by hypermethylation. These tumors often have \textit{BRAF} mutation (2, 4-6).

Molecular biomarkers in colorectal neoplasms have the potential to improve screening, aid in patient surveillance and diagnosis, indicate prognosis, predict response to chemotherapy, and serve as therapeutic targets or agents. MicroRNAs (miRNAs) are 17- to 22-nucleotide long non-coding endogenous single-stranded functional RNAs that regulate gene expression by regulating messenger RNA translation and degradation (7). MiRNAs can function as tumor suppressors or oncogenes depending upon the characteristics of their downstream targets, and alterations of
miRNA expression in colorectal neoplasms have been well-documented, especially differential miRNA profiles in adenocarcinoma as contrasted with non-neoplastic mucosa (8-22). Furthermore, differences in miRNA expression have been identified between microsatellite-stable and microsatellite instability-high colorectal cancers (15, 21,22).

Several studies have examined the colorectal adenoma that is the usual precursor to adenocarcinoma for expression of small numbers of selected miRNAs (9-13), and one study has used a global miRNA microarray approach (14). No previous study has addressed the small subset of adenomas that progress to adenocarcinoma. The paucity of data on miRNA alterations during the NM-A-AC sequence and the implications for the potential use of miRNAs as biomarkers and in therapeutic approaches led us to evaluate the differential expression of 866 human miRNAs by microarray analysis in 20 microsatellite-stable colorectal adenocarcinomas, their contiguous microdissected precursor adenoma, and nearby non-neoplastic mucosa. The aim of this study was to identify for the first time the patterns of variations in miRNA expression during the neoplastic progression that leads to the most frequent molecular subtype of colorectal cancer.

**Materials and Methods**

**Patients and sample preparation**

We searched the database of the Department of Pathology at The University of Texas MD Anderson Cancer Center and selected 21 patients who had invasive microsatellite-stable colorectal adenocarcinoma arising from a pre-existing adenoma and adjacent non-neoplastic mucosa in a resection specimen to permit pairwise analyses, and who had informed consent for
research use of their residual tissue. In one of these patients, adenocarcinoma was no longer present in the sections cut for RNA extraction and only adenoma and non-neoplastic mucosa were analyzed. All 20 adenocarcinomas and the 21 adenomas were microsatellite-stable by immunohistochemical analysis for nuclear expression of MLH1, MSH2, PMS2 and MSH6 mismatch repair proteins. Ten of the adenocarcinomas with remaining tissue were also microsatellite-stable on testing of DNA by PCR amplification of a panel of six National Cancer Institute Workshop-recommended microsatellite markers, as described elsewhere (23).

A hematoxylin and eosin (H&E)-stained slide from each formalin-fixed paraffin-embedded tissue block was used to select one block that had invasive adenocarcinoma and adenoma with low- and high-grade dysplasia with minimal contamination by stromal and inflammatory cells, and adjacent full thickness non-neoplastic mucosa including the surface epithelium and proliferative zone. This approach provided intraspecimen consistency, and nine blocks contained all four tissue types. The H&E slide from each selected block was then marked with insoluble ink on the coverslip to delineate the tissue for extraction. Unstained recut slides with 5-micrometer sections and no coverslip were laid over the marked slide, and the corresponding demarcated areas were manually microdissected. Clinical and pathologic characteristics are provided in Supplementary Table S1. The study was approved by The University of Texas MD Anderson Cancer Center Institutional Review Board.

**Total RNA labeling and hybridization**

All specimens from each case were processed and analyzed simultaneously to avoid bias. Total RNA, including miRNAs, was isolated from the microdissected deparaffinized tissue with the
RecoverALL TM Total Nucleic Acid Isolation Kit (Ambion, Inc., Austin, TX) and labeled using the miRNA Complete Labeling and Hyb kit (Agilent Technologies, Santa Clara, CA). Each labeled sample was hybridized to the Human miRNA Microarray Kit (V3, Agilent) containing oligonucleotide probes for 866 human miRNAs and 89 human viral miRNAs (Product Number G4470C, Design ID 021827) according to the miRNA Microarray System Protocol version 2.1. Twelve viral miRNAs were found to have statistically significant differences in expression, but their relevance was uncertain and these were not considered further.

**MicroRNA data processing and statistical methods**

Microarray data were processed using the statistical R package, Limma (Linear Models for Microarray Data) (24). A linear mixed-effects model was fitted to the expression of each miRNA to identify differentially expressed miRNAs in the adenoma-adenocarcinoma sequence. The Beta-Uniform Mixture method was applied to control false discovery rate (FDR) (25). Hierarchical clustering analysis was performed using Pearson correlation coefficients as distance metric and Ward’s linkage rule. The robustness of sample clusters was verified by a bootstrapping method with 200 iterations. Principle component analysis was conducted to examine the data structure composed of multiple miRNA expressions. Pairwise comparisons were performed by the simultaneous inference procedure (26). $P$ values $\leq 0.05$ were considered statistically significant. Further details are provided in Supplementary Text S2.

**Real-time quantitative polymerase chain reaction (qRT-PCR) for miRNA expression**

To confirm the miRNA signature derived from the microarray analysis, ABI TaqMan® miRNA assays (Applied Biosystems Inc., Foster City, CA) were performed with the manufacturer’s
protocol for six selected miRNAs. Briefly, 7 ng of total RNA were reverse transcribed with RNase inhibitor, MultiScribe RT enzyme, and miRNA-specific stem-loop primer (Applied Biosystems, Inc, Foster City, CA). The RT reaction was used subsequently in TaqMan® miRNA real-time PCR with the manufacturer’s protocol and an ABI 7900 Sequence Detection Instrument and associated software. Each sample was run in triplicate. RNU48 pre-developed assay (Applied Biosystems) was used as the normalizer. Further details are provided in Supplementary Text S2.

**Immunohistochemistry and quantitative image analysis for nuclear expression of beta-catenin**

Archival paraffin-embedded blocks of buffered formalin-fixed tissue from each case were used for immunohistochemistry with the polymeric biotin-free horseradish peroxide (HRP) method (Leica Microsystems, Richmond, IL.) on a Bond Max Stainer (Vision Biosystems, Norvell, MA). Briefly, sections were cut at 4-um thickness onto positively charged slides, pretreated with enzyme-induced epitope retrieval, and incubated with primary beta-catenin antibody (mouse antibody clone 14, 1:500, BD Biosciences, San Diego, CA). The Refine Polymer Detection Kit was used for immunostaining with 3, 3-diamiobenzidine serving as chromagen.

Immunohistochemistry sections were evaluated by light microscopy for nuclear expression of beta-catenin. Areas of histopathologically identified non-neoplastic mucosa, low-grade and high-grade dysplasia in adenoma, and adenocarcinoma were demarcated with permanent ink on the coverslips. No nuclear expression was found in non-neoplastic mucosa. Nuclei positive for beta-catenin in adenomas and adenocarcinomas were quantitated by automated image analysis at 20X.
magnification using the Aperio ScanScope XT (Aperio Technologies, Inc., 1360 Park Center Dr., Vista, CA 92081) and Aperio Genie Pattern Recognition software with a custom Genie Training Macro that was 98% sensitive and specific in separating tumor from stroma. Genie Nuclear Algorithm version 9.1 was then used to create a custom beta-catenin classifier with curvature threshold adjustment to de-cluster closely apposed nuclei and with reduced cytoplasmic intensity to avoid false-positives. All algorithm adjustments were tested to assure accurate detection of positive and negative nuclei as visualized by light microscopy. Nuclear labeling index, defined as number of immunohistochemically positive nuclei divided by total number of nuclei expressed as percentage, was calculated for each adenocarcinoma, high-grade dysplasia, and low-grade dysplasia. Further details are provided in Supplementary Text S2.

The Friedman rank sum test was applied to test the null hypothesis of no difference in the beta-catenin labeling index in the progression from non-neoplastic mucosa to adenocarcinoma. Correlation between miRNA expression and labeling index in each tissue type of all specimens was measured using Spearman rank correlation coefficient.

**MiRNA target prediction and pathway identification**

The p values of the miRNAs differentially expressed between non-neoplastic mucosa and low-grade dysplasia and between high-grade dysplasia and adenocarcinoma were rank-ordered to identify the first ten miRNAs, all of which were up-regulated. Three miRNAs were statistically significantly differentially expressed in the comparison between low- and high-grade dysplasia, and these were down-regulated. We first made a graphical presentation of the comparisons in order to distinguish the five “common” steps in the non-neoplastic mucosa-adenoma-
adenocarcinoma sequence from the three “specific” steps, as shown in Fig. 1. The comparison between low- and high-grade dysplasia was not included in the common steps since only three miRNAs were statistically significantly differentially expressed.

We used the http://www.microrna.org resource to retrieve the genes predicted by the algorithm MIRANDA to be targeted by the statistically significant miRNAs considered above. We used PERL to sort the genes based on the number of common miRNAs that targeted them and generated four gene lists as follows: First, genes targeted in common by at least three of the eleven miRNAs significant in at least four pairwise comparisons (the ten most significantly differentiated miRNAs in four comparisons together with let-7i that was the only significantly differentiated miRNA in five comparisons, designated as the common steps). Second, genes targeted in common by at least three miRNAs of the ten most significant for the transition from non-neoplastic mucosa to low-grade dysplasia, designated specific step 1 (Fig. 1). Third, genes targeted in common by the two miRNAs significant for the transition between low- and high-grade dysplasia, designated specific step 2, and for which the microrna.org database provided results. Fourth, genes targeted in common by at least three miRNAs of the ten most significant for the transition from high-grade dysplasia to adenocarcinomas, designated specific step 3. We then used ‘DAVID’ Bioinfomatics Resources 6.7 (http://david.abcc.ncifcrf.gov/) to determine the pathways involving these genes (Supplementary Table S3). To confirm the involvement of the Wnt signaling pathway during the earliest transition from non-neoplastic mucosa to low-grade dysplasia, we also examined the results from other miRNA target prediction algorithms: microT (http://diana.cslab.ece.ntua.gr/microT/), TargetScan (http://www.targetscan.org/), and PITA (http://genie.weizmann.ac.il/pubs/mir07/) (Supplementary Table S4).
Results

Altered miRNA expression in the non-neoplastic mucosa-adenoma-adenocarcinoma sequence

We evaluated the microRNAome in 69 matched specimens microdissected from one histopathologic section with a microsatellite-stable colorectal adenocarcinoma arising in a contiguous precursor adenoma and nearby non-neoplastic mucosa of 21 patients (Fig. 1). In one of the patients with adenocarcinoma, the histopathologic sections recut for the study had only non-neoplastic mucosa and villous adenoma with low- and high-grade dysplasia remaining (Supplementary Table S1). The adenocarcinoma therefore could not be analyzed for miRNA expression, resulting in a study set with 20 cancers.

230 miRNAs were identified to be differentially expressed in the NM-A-AC sequence by the linear mixed-effect model (FDR < 0.01). Two-way unsupervised hierarchical cluster analysis of the expression of these miRNAs resulted in discovery of three major clusters of tissue types (Fig. 2). The clusters were confirmed by the bootstrapping method. The first cluster was composed exclusively of non-neoplastic mucosae; the second mainly of non-neoplastic mucosae and low-grade dysplasias in adenomas with a few high-grade dysplasias and adenocarcinomas; and the third mainly of adenocarcinomas with a few admixed low- and high-grade dysplasias. The association between these clusters and disease progression as represented by the four tissue types was highly statistically significant (p < 0.001 by Fisher exact test). Principle component analysis revealed that non-neoplastic mucosae and adenocarcinomas were relatively separable from each
other, and that samples with high- or low-grade dysplasia in adenomas were generally mixed together with the adenocarcinomas (Supplementary Fig. S5).

Pairwise comparisons among the four tissue types in the NM-A-AC sequence identified marked differences in the number of differentially expressed miRNAs (Fig 3). The largest number, 216 of the 230 altered miRNAs, was differentially expressed between non-neoplastic mucosa and adenocarcinoma, followed by 144 between mucosa and high-grade dysplasia in adenomas, 134 between mucosa and low-grade dysplasia, 99 between low-grade dysplasia and adenocarcinoma, 25 between high-grade dysplasia and adenocarcinoma, but only 3 between low-grade and high-grade dysplasia.

Thirty-six miRNAs were significantly differentially expressed along the entire sequence as represented by all four comparisons between non-neoplastic mucosa paired with the three types of neoplasm and low-grade dysplasia paired with adenocarcinoma (Fig. 3). Upregulated and downregulated miRNAs were found among the 36, and the extent of changes was variable. Of the 16 upregulated miRNAs, 11 were increased two-fold or greater during progression (miR-7, -19a, -20a, -21, -22, -24, -34a, -34b, -224, and -331-3p and let-7i; range 2-6 fold), including five that were increased more than two-fold at the earliest step between mucosa and low-grade dysplasia (miR-20a, -21, -24, -34a, and -224), and eight that were increased from two- to four-fold between mucosa and high-grade dysplasia (miR-7, -19a, -20a, -21, -24, -34a, -34b, and -224). Three miRNAs were decreased at least two-fold (miR-188-5p, -650, and -671-5p). Nineteen of the miRNAs were not previously described as altered in colorectal adenocarcinoma, to our knowledge (miR-130b, -188-5p, -202, -331-3p, -371-5p, -455-3p, -520b, -513a-5p, -601, -
617, -636, -650, -671-5p, -708, -939, -1224-5p, -1225-5p, -1226, and -1308). None of the 36 miRNAs was significantly differentially expressed when analyzed for site in the colorectum, age, gender or stage of disease after adjustment for within-patient correlation.

**Confirmation of altered expression of selected miRNAs**

The differential expression detected by microarray analysis was evaluated by qRT-PCR for six selected miRNAs. Two were chosen to confirm miRNAs previously described as altered in colorectal adenomas and/or adenocarcinomas (miRs-17 and -224) (8,12,14,18,19,27) and four (miR-130b, -601, -939, and -1225-5p) to confirm miRNAs not previously described as altered in colorectal neoplasms. [MiR-130b is a paralogous sequence of miR-130a that had been described previously as altered (28).] The microarray results were confirmed for all six miRNAs (Supplementary Table S6).

**Patterns of altered miRNA expression in the non-neoplastic mucosa-adenoma-adenocarcinoma sequence**

Grouping of the pairwise comparisons among the four tissue types that had statistically significant differences revealed two major patterns of altered miRNA expression (Fig. 3, Fig. 4, and Supplementary Table S7). The first major pattern resulted from 134 miRNAs with early altered expression in which significant changes occurred at the first step in the NM-A-AC sequence, i.e. between mucosa and low-grade dysplasia in adenomas, and was designated as *Type 1 pattern*. The second major pattern was composed of 96 miRNAs with later alteration of expression, designated as *Type 2 pattern* that was not present in low-grade dysplasia.
Subgroups were evident within these two major groups. In the *Type 1* pattern, 108 miRNAs had altered expression that persisted throughout the progression from low-grade dysplasia through high-grade dysplasia to adenocarcinoma, termed the *early persistent pattern* that was comprised of *Subtype 1A miRNAs* (Fig. 3 and Fig. 4). This group included the 36 miRNAs identified from the pairwise comparisons of the four tissue types, along with 72 others. A second subgroup of 20 miRNAs had an *early intermittent pattern* of alteration during progression and was designated as *Subtype 1B miRNAs*. These miRNAs had significant changes in expression between mucosa and low-grade dysplasia and between mucosa and adenocarcinoma that did not persist between mucosa and high-grade dysplasia. The third subgroup consisting of six miRNAs had an *early transient pattern* of differential expression and was termed *Subtype 1C miRNAs*. Although different between mucosa and adenoma, the early altered expression in these six miRNAs did not persist between mucosa and adenocarcinoma.

Within the group of miRNAs with the *Type 2* late pattern (n=96) that lacked altered expression at the earliest step between mucosa and low-grade dysplasia, 33 miRNAs were altered in the mid portion of the NM-A-AC sequence, resulting in a *late intermediate pattern* of *Subtype 2A miRNAs*. These miRNAs differed between mucosa and high-grade dysplasia and adenocarcinoma (Fig. 3 and Fig. 4). The final subgroup of 63 miRNAs was altered only late, at the step of adenocarcinoma. This *late pattern*, resulting from *Subtype 2B miRNAs*, had significantly altered expression between adenocarcinoma and mucosa or dysplasia, but not between mucosa and the pre-malignant tissue types.

**Patterns of altered miRNA expression and beta-catenin localization**
We compared the miRNA alteration patterns to nuclear beta-catenin localization because dysregulation of the WNT signaling pathway resulting from mutation of the APC gene is well-known to be an important early step in colorectal tumorigenesis and leads to abnormal beta-catenin translocation into tumor cell nuclei, although Wnt activation can also occur in the absence of detectable nuclear beta-catenin accumulation (29-31). We found no nuclear localization of beta-catenin in non-neoplastic mucosa. The means and standard deviations of the beta-catenin nuclear labeling indices by immunohistochemistry and morphometric image analysis were 3.8 ± 1.4% (range 1.6-6.5%) for low-grade dysplasia in adenomas, 7.1 ± 2.7% (range 2.9-10.7%) for high-grade dysplasia in adenomas, and 9.1 ± 7.8% (range 1.2-30.5%) for adenocarcinomas (p=.01 by Friedman rank sum test). Thus, the Type 1 early alterations in miRNA expression preceded major nuclear localization of beta-catenin.

In our exploratory analysis, we found statistically significant correlation (p<.05, absolute value of Spearman correlation coefficients > 0.56) between nuclear labeling index for beta-catenin and expression levels of 23 miRNAs, most included in Subtype 1A, in adenomas with low-grade dysplasia. Thirteen of these miRNAs were positively correlated with nuclear beta-catenin expression (let-7a and miR-22, -30d, -95, -98, -99b, -127-3p, -130a, -133a, -151-3p, -185, -196b, and -425), and ten were inversely correlated (miR-184, -498, -500, -501-5p, -520-3p, -617, -877, -921, -1288, and -1305). In addition, we observed that the correlation between miRNA expression and labeling index was stronger in adenomas with low-grade dysplasia than in adenocarcinoma (bimodal distribution of correlation coefficients in adenomas as contrasted with distribution around zero in carcinomas; Fig. 5).
MiRNA-targeted pathways in the non-neoplastic mucosa-adenoma-adenocarcinoma sequence

To gain further insight into the possible roles of abnormally expressed miRNAs during the NM-A-AC sequence, we used the [http://www.microrna.org/](http://www.microrna.org/) data resource and ‘DAVID’ Bioinformatics Resources version 6.7 to perform searches for the predicted targets, followed by Gene Ontology Pathway Analysis of the commonly predicted targets (Fig. 6 and Supplementary Table S3). We identified let-7i as the only miRNA differentially expressed in all five pairwise comparisons (p < 0.05; max p-value=2.87E-02). Ten additional miRNAs were significantly differentially expressed in four of six pairwise comparisons (p < 0.01). Eight of these miRNAs (miR-7, -21*, -224, -34b*, -34a, -193a-3p, -21, -19a) were up-regulated during all steps from mucosa to low-grade dysplasia to high-grade dysplasia to adenocarcinomas, whereas one (miR-320a) was down-regulated. These 9 miRNAs were members of Subtype IA. The tenth miRNA (miR-133b) was down-regulated from mucosa to low-grade dysplasia and from mucosa to high-grade dysplasia, but up-regulated from both low- and high-grade dysplasia to adenocarcinoma.

Upon further analysis of let-7i and the ten miRNAs described above, we identified significantly enriched (P<0.05) targets in 12 pathways, including the MAPK signaling pathway (P<0.001) that contains the FGRBR1 gene and 35 other members. We also identified three pathways in common (Wnt Signaling Pathway, Melanoma, and Pathways in Cancer) during the early two-step transition from mucosa to high-grade dysplasia (Supplementary Table S3). More importantly, when we determined the gene pathways affected by altered miRNAs in the three specific steps from mucosa to low-grade dysplasia, low- to high-grade dysplasia, and high-grade dysplasia to adenocarcinoma, we found that in the earliest step of colorectal tumorigenesis (mucosa
compared with low-grade dysplasia) the Wnt pathway that is well-known to be aberrant in colorectal adenocarcinoma was involved (P=0.001). In addition, eight of the altered miRNAs (miR-20a, -23a, -25, -27a, -34a, -92a, -148a, and -203) had nine identified targets in the canonical, planar cell polarity, and calcium ion components of the Wnt pathway (Fig. 6, Table 1) with redundancy in the miRNAs affecting each target, and each miRNA having multiple targets in the Wnt pathway. The Wnt signaling pathway also appeared significant when using the followings algorithms: microT (http://diana.cslab.ece.ntua.gr/microT/), TargetScan (http://www.targetscan.org/), and PITA (http://genie.weizmann.ac.il/pubs/mir07/) (Supplementary Table S4).

Pathway analysis of targets for miRNAs we found were correlated with beta-catenin nuclear expression revealed that downregulated miRs-617 and -498 (Subtype 1A) were predicted to regulate beta-catenin (Fig. 6). These predictions affirm the seminal importance of altered Wnt signaling in colorectal tumorigenesis and indicate that variations in expression of multiple genes in the pathway provide a mechanism for dysregulation. Because APC mutation is uncommon in adenomas, our findings also suggest that abnormal regulation by miRNAs is among the earliest steps in colorectal adenoma development.

**Discussion**

Our study expands understanding of the complex roles of miRNAs in colorectal tumorigenesis. Numerous published studies have addressed miRNAs in colorectal cancer (reviewed in reference 8), but few have reported on the NM-A-AC sequence (9-14). These studies have evaluated small
numbers of selected miRNAs (9-13) or a miRNA profile (14) without concentration on pairwise comparison of precursor tissues from the same neoplasm in order to reduce intertumoral heterogeneity within individual patients (9-14), the microsatellite instability status of the cancers (9-13), or the subset of adenomas that give rise to adenocarcinoma (9-14). By contrast, our study used a microRNAome profiling approach for paired specimens of microsatellite-stable adenocarcinomas that represent the most frequent molecular subtype and their contiguous precursor adenomas. We demonstrated extensive alterations in miRNA expression with frequent early changes (n=134 Type I miRNAs) and found five subpatterns that indicate the complexity of the miRNA alterations, including the timing of the alterations during progression.

Previous studies of colorectal adenomas that addressed specific miRNAs have reported alterations compared to non-neoplastic mucosa for six members of the miR-17-92 cluster (12) and miR-21 (11), -135a and -135b (10), -137 (13), and -143 and -145 (9). The previously reported profiling study (14) evaluating 735 miRNAs identified 31 that had > 2 fold change in expression in adenomas, including miR-135a, -135b, and -137 from the earlier reports, although miR-135a was found to have decreased expression in contrast to increased expression in the earlier report. We found among 866 miRNAs that miR-19a, -20a, -21, -92a, and -135b from the previous reports were altered. In addition to confirming the alteration of these miRNAs in adenomas, we expanded upon these previous results by identifying that all of these miRNAs had the early persistent pattern (Subtype 1A), suggesting that their alteration occurred early in tumorigenesis and was maintained. These repeatedly identified miRNAs, therefore, are likely drivers rather than consequences of neoplastic progression. Comparison of our findings with the other published profile analysis (14) identified 453 probes in common between the two studies.
Eleven miRNAs (miR-1, -96, -100, -133a, -135b, -182, -183, -224, -299-5p, -552, and -584) were altered in adenomas in both profiling studies, and 328 miRNAs were unaltered in adenomas in both (Supplementary Table S8). The concordance of results for 339 miRNAs occurred despite methodological differences in analysis platforms, miRNA annotation, and criteria for change in expression, as well as study design differences in patient populations, tissue types (frozen or formalin-fixed paraffin-embedded), sample sizes, and relationship of the studied adenomas to adenocarcinoma (separate or contiguous). In addition, fifty of the miRNAs that were altered between non-neoplastic mucosa and adenoma in our study were reported previously to be altered in colorectal cancer (reviewed in reference 8). Our findings therefore emphasize the importance of numerous miRNAs in the early phase of colorectal tumorigenesis.

The biological meaning and clinical implications of the five subpatterns of miRNA alterations we observed remain to be explored fully. The majority of alterations occurred between non-neoplastic mucosa and adenomas with low-grade dysplasia when mutations of intensely studied genes, including APC, and other structural DNA alterations are uncommon (2) and before nuclear localization of beta-catenin was a prominent feature in our study. Intratumoral heterogeneity poses a challenge in understanding these cellular events because miRNA expression represents the net result of levels in the population of evaluated cells, and mechanistic studies are therefore needed to explain our observations. From the clinical perspective, we identified among the large number of Type 1 miRNAs a set of 36 that had significantly increased or decreased expression throughout the entire progression from non-neoplastic mucosa to adenoma and adenocarcinoma. These miRNAs are likely to be of interest for exploration as markers and as therapeutic targets (32) and agents (33) due to their ubiquitous changes. We
identified throughout progression the deregulated expression of 19 miRNAs not previously described in colorectal adenocarcinoma to our knowledge. In addition, we describe for the first time the relationships among the individual steps in morphologic progression along the NM-A-AC sequence and dysregulation of numerous miRNAs. These subtypes of miRNAs have potential as markers and therapeutic targets and agents with greater specificity for steps along progression than the ubiquitously altered miRNAs, although few miRNAs were altered between low-grade and high-grade dysplasia in adenomas that were contiguous with an adenocarcinoma in our study.

The subtypes of altered miRNA expression appear to be associated with propensity of the miRNAs to be detectable in plasma, affected by chemotherapy, and serve as therapeutic targets. Use of plasma miRNAs as biomarkers for early detection of colorectal neoplasia has been proposed (34-38). In plasma samples from patients with advanced adenomas, miR-29a and -92a (34) and miR-17-3p and -92 (36) that are all in our Subtype IA were associated with the presence of an adenoma, suggesting that plasma miRNA may have propensity to be derived from the early persistent subtype of miRNA. In addition, several studies have examined the effects of chemotherapy on miRNAs in human colon cancer cell lines (18,39). Three miRNAs (miR-16, -34a and -34b) that were increased in two human colon cancer cell lines treated with adriamycin (39) are in Subtype IA. Among these, miR-34a inhibited cell proliferation, contributed to induction of apoptosis and G1-arrest, down-regulated the E2F family of transcription factors, and both up-regulated and was a target for the p53 pathway (27). A study of the effects of 5-fluorouracil (5-FU), the most commonly used chemotherapeutic agent for colorectal cancer, in human colon cancer cell lines (18) found nineteen miRNAs upregulated and three down-
regulated. Fifteen of these miRNAs (miR-19a, -20, -21, -23a, -25, -27a, -27b, -29a, -133a, -135b, -151, -182, -185, -210 and -224) are in our Subtypes 1A and 1B.

Among the novel miRNAs we found, we confirmed by qRT-PCR the alteration of four of interest, including the upregulation of miR-130b. A recent study described this miRNA as rescuing human mammary epithelial cells from Ras-induced senescence by preventing RasG12V-induced upregulation of the cell cycle inhibitor p21Waf1/Cip1 (40) that is known to downregulate expression of thymidylate synthase, a target enzyme of 5-FU (41). Three other downregulated novel miRNAs, miR-601, -939, and -1225-5p, are in Subtype 1A and have a variety of targets of interest. Putative targets of miR-601 include tyrosine 3-monooxygenase/tryptophan 5-monooxygenase activation protein zeta polypeptide (YWHAZ) in the 14-3-3 family that mediates signal transduction (Targetscan 5.1) and that is implicated in carcinogenesis (42), and aquaporin-1 that mediates membrane permeability in human colon cancer cell lines and affects invasion and metastasis (43). Reported targets of miR-939 include RasL10B that is down-regulated in human breast cancer cell lines, suggesting that this miRNA may be a tumor suppressor (44), and tumor necrosis factor alpha that has been associated with clinical characteristics of colorectal tumors (45). A putative target of miR-1225-5p is HIC2 (hypermethylated in cancer 2)/HRG22 (HIC1-related gene on chromosome 22) that has been identified as a tumor suppressor gene (46) and is transcriptionally inactivated in numerous human cancers including colorectal carcinoma (47, 48). Another possible target is the Paternally Expressed 10 (PEG10) gene that is overexpressed in hepatic adenomas and hepatocellular carcinomas (49, 50).
In conclusion, we speculate that the five patterns of miRNA alterations we identified in the NM-A-AC sequence reflect both primary events and processes that are reactive and adaptive to previous genetic, epigenetic, and miRNA alterations. The large number of miRNAs (n=134) that we found to be altered between non-neoplastic mucosa and low-grade dysplasia in adenomas (Type 1 pattern) at the outset of the NM-A-AC sequence likely produces early dysregulation of numerous cellular pathways (51). As a result, understanding of the mechanisms for and consequences of these complex early miRNA changes may provide important insights into potential strategies to prevent progression that leads to cancer in the NM-A-AC sequence. The late alterations (Type 2 pattern) may provide information on mechanisms of benign to malignant conversion. Understanding the nature of the alterations is essential to effective use of miRNAs as biomarkers and therapeutic targets or agents since many of the alterations are linked to steps in the sequence.

Figure Legends

Fig. 1. Photomicrograph illustrating the non-neoplastic mucosa-adenoma-adenocarcinoma sequence and histopathologic identification of tissue areas for microdissection, RNA extraction, and microRNAome profiling. The four boxes from left to right indicate non-neoplastic mucosa, villous adenoma with low-grade dysplasia, high-grade dysplasia in the adenoma, and contiguous adenocarcinoma invading submucosa, respectively. Graphic presentation of comparisons to
distinguish “common” pathways (red arrows) from “specific” pathways (blue arrows) for our pathway analysis is also illustrated.

Fig. 2. Two-way unsupervised hierarchical clustering of the 230 differentially expressed miRNAs in the four tissue types with non-neoplastic mucosa indicated by orange bars, low-grade dysplasia in adenoma by cyan green bars, high-grade dysplasia in adenoma by purple bars, and invasive adenocarcinoma by blue bars. Black represents no alteration of expression; pure red, +3 and higher expression; and pure green, −3 and lower expression. Three clusters of tissue types are evident. The first is composed exclusively of non-neoplastic mucosae; the second mainly of non-neoplastic mucosae and low-grade dysplasias in adenomas and a few high-grade dysplasias and adenocarcinomas; and the third mainly of adenocarcinomas with a mixture of low-grade and high-grade dysplasias. The association between these clusters of miRNAs and disease progression represented by the four tissue types was highly significant (p < 0.001, Fisher exact test).

Fig. 3. Pairwise comparisons of non-neoplastic mucosa with low-grade dysplasia in adenoma (NM:ALG), with high-grade dysplasia in adenoma (NM:AHG), and with adenocarcinoma (NM:CA); and between low-grade or high-grade dysplasia and adenocarcinoma (ALG:CA and AHG:CA, respectively). Each row represents the p values for each pairwise comparison for the miRNA listed in the right column. The Type 1 pattern is defined by miRNAs that are altered between mucosa and low-grade dysplasia and includes three subtypes of miRNAs with early persistent (1A), early intermittent (1B), and early transient (1C) alterations. The Type 2 pattern is evident for miRNAs that are not altered in expression between mucosa and low-grade dysplasia
but are altered late in the non-neoplastic mucosa-adenoma-adenocarcinoma sequence. MiRNAs with late intermediate (2A) and late (2B) alterations are illustrated.

Fig. 4. Illustration of the five patterns of altered miRNA expression for individual patients. The Type 1 pattern is defined by miRNAs that are altered between non-neoplastic mucosa and low-grade dysplasia and includes three subtypes of miRNAs with early persistent (1A), early intermittent (1B), and early transient (1C) alterations. The Type 2 pattern is evident for miRNAs that are not altered in expression between mucosa and low-grade dysplasia but are altered late in the mucosa-adenoma-adenocarcinoma sequence. MiRNAs with late intermediate (2A) and late (2B) alterations are evident.

Fig. 5. Histograms of Spearman rank correlation coefficients between levels of miRNA expression and nuclear beta-catenin labeling indices. The X-axis has the correlation coefficient values, and the Y-axis indicates the percentage of the 230 miRNAs that were differentially expressed in the non-neoplastic mucosa-adenoma-adenocarcinoma sequence with the corresponding correlation coefficient values. A biomodal distribution is evident in adenomas with low-grade dysplasia (ALG) indicating that numerous miRNAs have positive or inverse correlation of their expression with beta-catenin expression. By contrast, carcinomas (CA) have a normal distribution with only small numbers of miRNAs with expression correlated with beta-catenin expression. The findings indicate the importance of miRNA alterations at the earliest step in tumorigenesis.
Fig. 6. Members of WNT signaling pathway predicted by MIRANDA algorithm to be targeted by miRNAs that are significantly differential expressed early in the mucosa-adenoma-adenocarcinoma sequence (yellow) or that are significantly correlated with nuclear expression of beta-catenin (orange).
Complex Patterns of Altered MicroRNA Expression during the Adenoma-Adenocarcinoma Sequence for Microsatellite-stable Colorectal Cancer
