STATEMENT OF TRANSLATIONAL RELEVANCE

Conventional radioimmunotherapy (RIT) induces long-term durable remissions in over 50% patients with relapsed or refractory indolent non-Hodgkin's lymphoma (NHL). Our research goal is to optimize RIT using a multistep pretargeted RIT scheme (PRIT) employing genetically engineered mutant-streptavidin fusion proteins and bis-biotin reagents that provide an attractive alternative to current methods. This molecular engineering approach is particularly attractive in clinical settings where high endogenous biotin levels prevail due to dietary intake of this vitamin, leading to diminished efficacy of standard streptavidin/ biotin reagents.

We anticipate that this approach will result in superior efficacy compared to both conventional RIT and current PRIT approaches. If the results are promising, we anticipate eventually translating this approach into phase I/II clinical studies of PRIT for patients with relapsed B cell lymphomas.
ABSTRACT

Purpose: Pretargeted radioimmunotherapy (PRIT) using streptavidin (SAv)-biotin technology can deliver higher therapeutic doses of radioactivity to tumors than conventional RIT. However, “endogenous” biotin can interfere with the effectiveness of this approach by blocking binding of radiolabeled biotin to SAv. We engineered a series of SAv FPs that down-modulate the affinity of SAv for biotin, while retaining high avidity for divalent DOTA-bis-biotin to circumvent this problem.

Experimental Design: The single-chain variable region gene of the murine 1F5 anti-CD20 antibody was fused to the wild-type (WT) SAv gene and to mutant SAv genes, Y43A-SAv and S45A-SAv. FPs were expressed, purified and compared in studies using athymic mice bearing Ramos lymphoma xenografts.

Results: Biodistribution studies demonstrated delivery of more radioactivity to tumors of mice pretargeted with mutant SAv FPs followed by $^{111}$In-DOTA-bis-biotin (6.2 ± 1.7 % of the injected dose per gram [%ID/gm] of tumor 24 hours after Y43A-SAv FP and 5.6 ± 2.2 %ID/g with S45A-SAv FP) than in mice on normal diets pretargeted with WT-SAv FP (2.5 ± 1.6 %ID/g; p = 0.01). These superior biodistributions translated into superior anti-tumor efficacy in mice treated with mutant FPs and $^{90}$Y-DOTA-bis-biotin (tumor volumes after 11 days: 237 ± 66 mm$^3$ with Y43A-SAv, 543 ± 320 mm$^3$ with S45A-SAv, 1129 ± 322 mm$^3$ with WT-SAv and 1435 ± 212 mm$^3$ with control FP [p < 0.0001]).

Conclusions: Genetically engineered mutant-SAv FPs and bis-biotin reagents provide an attractive alternative to current SAv-biotin PRIT methods in settings where endogenous biotin levels are high.
INTRODUCTION

Despite advances in the management of lymphoma, fewer than 60% of patients with aggressive non-Hodgkin lymphomas (NHL) and fewer than 5% of patients with indolent lymphomas can be cured with conventional chemotherapy (1-3). The remaining patients eventually relapse, and the disease becomes progressively more chemotherapy-resistant. This does not preclude the therapeutic benefit of radiation therapy; however, since lymphoma cells remain highly susceptible to even low-doses of radiation regardless of their inherent resistance to chemotherapeutic drugs. For this reason, radioimmunotherapy (RIT) has emerged as a promising treatment option for NHL. RIT has yielded excellent overall response rates of 50% to 80%, with complete response rates of 20% to 40% in patients with relapsed or refractory indolent lymphoma treated with iodine-131 (\(^{131}\text{I}\)) tositumomab (Bexxar, GlaxoSmithKline) or yttrium-90 (\(^{90}\text{Y}\)) ibritumomab tiuxetan (Zevalin, Spectrum) (4-7). Nevertheless, most patients treated with conventional doses of RIT eventually relapse even after favorable initial responses. Dose-escalation of RIT to myeloablative levels with stem-cell support significantly reduces the risk of relapse by delivering potentially curative radiation doses to tumor sites. However, this approach has been associated with significant treatment-related morbidity and mortality (8-10).

One strategy for delivering higher, potentially curative, radiation doses to tumors involves a multi-step “pretargeting” method. The major cause of dose limiting toxicities in conventional RIT is due to the slow clearance of unbound radiolabeled antibodies (Ab) from the circulation with resultant high levels of background radioactivity in normal tissues (11-13). Pretargeted radioimmunotherapy (PRIT) dissociates the slow distribution phase of the Ab molecule from administration of the therapeutic radionuclide. This approach permits the tumor-reactive Ab to localize and accumulate at tumor sites.
without subjecting the rest of the body to nonspecific irradiation from circulating radiolabeled Ab (14-17). After maximal accumulation of Ab in the tumor, a small molecular weight radioactive moiety, which has high affinity for the tumor-reactive Ab is administered. This second reagent penetrates tumors rapidly due to its small size. Excess unbound molecules of the second radioactive reagent are also rapidly cleared from the blood and excreted in the urine due to their small size. To facilitate this process, a “clearing agent” (CA) may be injected before the radiolabeled small molecule to enhance elimination of the unbound Ab from the bloodstream thus preventing it from complexing with the radiolabeled small molecule in the circulation.

Preclinical data have demonstrated that streptavidin (SAv)-biotin pretargeting strategies can dramatically increase the tumor-to-normal organ ratio of delivered radioactivity by 10 to 100 fold (16-18). Pilot clinical trials have also demonstrated promising results in both solid tumor and lymphoma models, though the outcomes were not as dramatic as those observed in preclinical studies (19-22). Suboptimal responses observed in the pilot clinical trials may be partially attributable to the presence of competing endogenous biotin in patient serum, derived from dietary sources. Biotin is present in blood and tissues at sufficient concentrations to irreversibly block the biotin binding sites of SAv and may impair its efficacy in pretargeting applications (21),(23). In preclinical studies, mice may be fed a biotin-deficient diet for several days prior to the therapy to reduce the endogenous biotin concentration in serum. In contrast, biotin-depletion in human clinical trials is more problematic due to the ubiquitous presence of this vitamin in all common foods, patient non-compliance, and concerns over complications attributable to biotin deficiency. Although the serum concentration of biotin present in humans is somewhat lower than in mice, endogenous biotin remains a significant concern, particularly because the liver acts as a storage and release-reservoir for biotin (24). Strategies that
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

avoid the blocking of the biotin-binding sites of SAv by endogenous biotin may therefore offer therapeutic advantages. To address this issue, Stayton and colleagues produced a large library of SAv variants by site-directed mutagenesis directed at the SAv binding pocket (Table S1), covering a wide range of $K_a$ and $K_{off}$ properties (25-26). Along with the engineering of SAv mutants, divalent bis-biotin ligands were designed to effectively engage two adjacent biotin binding sites of SAv mutants, thus overcoming the competitive binding by endogenous biotin (27-29). The lower affinities and faster biotin off-rates of the SAv mutants allow exchange of pre-bound endogenous biotin, while the dual binding of the bis-biotin ligand results in a striking avidity effect and essentially irreversible capture of the modified divalent ligand (27, 30-32). In this manuscript, we describe the synthesis and characterization of two SAv mutant fusion proteins (FPs), S45A-SAv and Y43A-SAv. The FPs were selected based on previous kinetic studies suggesting they were the most promising candidates that would allow exchange of pre-bound monovalent endogenous biotin while retaining sufficiently high affinity to efficiently capture radiolabeled divalent bis-biotin ligands (27, 29). We report here the blood clearance of the mutant-SAv FPs using a standard monovalent biotin CA or a novel bivalent biotin CA, specifically designed for this application. Finally, we compare the targeting, biodistributions, and therapeutic efficacy of PRIT strategies utilizing either conventional wild type (WT)-SAv and biotin or mutant-SAv and bis-biotin reagent combinations.

MATERIALS AND METHODS

Cell culture
The human Ramos Burkitt lymphoma cell line was obtained from the American Type Culture Collection (ATCC). Cell lines were maintained in log phase growth in RPMI 1640 medium supplemented with 10% heat-inactivated fetal calf serum in a 5% CO₂ incubator. Cell viability exceeded 95% by trypan blue exclusion.

**WT-SAv FP and mutant-SAv FPs**

The development of the 1F5-WT-SAv FP has been previously described (33-35). Briefly, the process involved fusion of the single-chain variable regions (scFv) of the murine anti-CD20 1F5 Ab to the full length genomic SAv of *Streptomyces avidinii* wild type (WT) gene to obtain the 1F5(scFv)₄SAv fusion gene. This gene construct was modified by PCR-based site-directed mutagenesis to produce mutant genes carrying either the S45A or the Y43A mutations, with an SSGSGSA peptide linker between the SAv and the scFv genes in each construct. The residue changes in fusion genes were determined by DNA sequencing analysis, and the gene products were analyzed by mass spectroscopy, which indicated all FPs differed only at the deliberately engineered positions without any extraneous mutations (data not shown). *E. coli* XL1 Blue (Stratagene) transformants of the gene constructs, WT-SAv, S45A-SAv, or Y43A-SAv, were grown in shaker flasks under control of an IPTG inducible lac promoter for qualitative expression of the FPs. A 4 L fermentor (BioFlo 3000; New Brunswick Scientific) was used for bulk production of FPs. The FPs were purified by iminobiotin chromatography as described (18), except that the loading pH was raised from 9.2 to 11 due to the reduced affinities of the mutant FPs for iminobiotin. (33-35). Aggregates were reduced to ~3% by treatment with 20% DMSO. The eluted FPs were dialyzed against phosphate buffered saline (PBS) at 4 °C overnight and concentrated to 2.0-2.3 mg/ml using a YM30 membrane. The final FPs were filter-sterilized and stored in 5% sorbitol at -80 °C. A negative control FP (CC49-
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

WT-SAv) that recognizes the TAG 72 antigen expressed on human adenocarcinomas, but not on lymphomas, was prepared similarly.

**Pretargeting reagents**

A synthetic, dendrimeric CA containing 16 N-acetylgalactosamine residues and a single biotin residue per molecule (NAGB) was obtained from Aletheon Pharmaceuticals for use with 1F5-WT-SAv FP, as described previously (35). A bis-biotin-trigalactose (BBTG) CA containing two biotin moieties and three galactose residues \( (\text{C}_{127}\text{H}_{218}\text{N}_{19}\text{O}_{51}\text{S}_6) \) was used for the clearance of mutant-SAv FPs. The syntheses of BBTG CA and DOTA-bis-biotin have been recently described (28).

**Radiolabeling of biotin compounds**

\(^{111}\text{In}\) labeling of DOTA-biotin and DOTA-bis-biotin were conducted as published (28). \(^{90}\text{Y}\) labeling for therapy was performed similarly, using 2 mg/mL DOTA-bis-biotin, 500mM ammonium acetate pH 5.3 and \(^{90}\text{Y}\) heated for 30 minutes at 85°C. After cooling to room temperature, 100 mM DTPA was added.

**In vitro characterization**

The FPs were analyzed by SDS-PAGE on 4-12% Tris-glycine gels (Invitrogen) under non-reducing conditions. The gels were stained with 0.2% Coomassie blue solution and de-stained in acetic acid-methanol solution. Size-exclusion high-performance liquid chromatography (HPLC) analysis was performed on a Zorbax GF-250 column (9.4 x 250 mm, 4μm; Agilent) with 20 mM sodium phosphate/0.5 M sodium chloride/15% dimethyl sulfoxide (DMSO; pH 6.8-7.0) as a mobile phase (1ml/min) and \( A_{280} \) as a detection wavelength on a Dynamax system. Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry performed on a Voyager DE Pro MALDI time-of-flight mass
spectrometer (Applied Biosystems) was used to ascertain the molecular weight of the FPs. The CD20 binding ability of the FPs was assessed using PE-biotin labeled FPs and Ramos target cells. Cells (0.1 X 10^6 per sample) were incubated with 30 μl of 10 μg/ml 1F5 (positive control) Ab, HB8181 (non-binding isotype control) Ab, 1F5-Y43A-SAv FP, 1F5-S45A-SAv FP, 1F5-WT-SAv FP, or CC49-WT-SAv FP (negative control) for 30 minutes at 4°C. Cells were washed and incubated with 30 μl 1:64 goat anti-mouse IgG (Fab specific) FITC conjugate (Sigma-Aldrich) in PBS. Cells were washed and fluorescence intensity was measured on FACS Canto I flow cytometer (BD). An in vitro cell binding assay was also performed by incubating Ramos cells (1.0 X 10^6 per sample) with 25 μl of 20ug/ml 1F5-Y43A-SAv, 1F5-S45A-SAv, 1F5-WT-SAv, or CC49-WT-SAv FPs in a 96 round bottom ELISA plate at 4 °C for 60 minutes. Cells were then washed twice in 200 μl PBS. Next, similar molar amounts of ^90^Y-DOTA–biotin (100 ng/ml) or ^90^Y-DOTA–bis-biotin (100 ng/ml) were added to the cells and incubated at 4°C for 60 minutes. Cells were washed twice with PBS. Cells were collected using cotton swabs and ^90^Y activity measured in a gamma counter.

**Blood clearance studies**

Three groups of four athymic mice each were injected via the tail vein (i.v.) with ^125^I-1F5-Y43A-SAv or ^125^I-1F5-S45A-SAv FPs (2.8 nmol) followed 24 hours later by i.v. injection of 5.8 nmol of either NAGB or BBTG CA. Venous sampling was performed via the tail vein at serial time points up to 68 hours. ^125^I was counted on a gamma counter and the percent of the injected dose per gram (%ID/g) of blood was calculated.

**Mouse Xenograft Model**

FoxN1^Nu^ athymic female mice (6-8 weeks old) were obtained from Harlan Sprague-Dawley and housed in the FHCRC animal facility after approval of the experimental
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

protocol by the Institutional Animal Care and Use Committee. Some groups of mice were switched to a biotin-deficient diet (Purina Mills) 5-6 days prior to PRIT studies. Ramos cells (10 x 10^6) were injected subcutaneously in the right flank 10 days prior to experiments to produce lymphoma xenografts measuring 6 - 10 mm in diameter. Anti-asialoGM1 antiserum (30 µl, WAKO) was injected 9 days and 6 days prior to FP injection to abrogate natural killer cell activity and prevent spontaneous tumor regressions.

Biodistribution studies

Biodistribution experiments were performed using the "double label" method of Pressman by trace-labeling the 1F5-SAv FPs with ^125^I and the biotin moiety with ^111^In to allow independent assessment of tumor targeting of the FPs and the biotin ligands (36). Groups of 5 mice with similar-sized tumors were injected i.v. with 2.8 nmol (400 µg) of 1F5-WT-SAv, 1F5-Y43A-SAv or 1F5-S45A-SAv FPs labeled with 20-40 µCi (0.74-1.48 MBq) of ^125^I. Twenty hours later, mice were injected with either 5.8 nmol of NAGB CA (50 µg) followed 4 hrs later by 1.2 nmol DOTA-biotin labeled with 20-40 µCi (0.74-1.48 MBq) of ^111^In or with 5.8 nmol of BBTG CA (20 µg) followed 4 hrs later by 1.2 nmol of ^111^In -DOTA-bis-biotin. Blood samples, tumors, and body organs were procured and ^125^I and ^111^In activities measured in a dual channel gamma counter, adjusting for cross-over between channels (17).

Therapy studies

The therapeutic efficacy of ^90^Y using various pretargeted approaches was evaluated in groups of 5 to 10 mice. Groups of mice with similar-sized, palpable tumors were selected and randomized for the studies. Mice were given 2.8 nmol (400 µg) of 1F5-WT-SAv, 1F5-Y43A-SAv, 1F5-S45A-SAv, or the negative control CC49-WT-SAv followed by 5.8
nmol of either NAGB or BBTG CA 20 hrs later. A single dose of 1.2 nmol of either
DOTA-biotin or DOTA-bis-biotin labeled with 500 μCi (18.5 MBq) $^{90}$Y was administered 4
hrs after the CA. Mice were assessed every few days for tumor volume measurements,
weight change, and general appearance. Mice were euthanized if xenografts exceeded
10% of total body weight, caused obvious discomfort or impaired ambulation, or if mice
lost more than 30% of their baseline body weight.

Toxicity studies
Toxicity studies were performed in parallel cohort groups, corresponding to the therapy
groups. Mice were monitored for lethargy, poor grooming, weight loss and other
behaviors consistent with debility. Blood testing was performed 14 days after injection of
$^{90}$Y, and at the time of euthanasia. Laboratory tests performed included the leukocyte
and platelet counts, hemoglobin, aspartate aminotransferase (AST), alanine
aminotransferase (ALT), creatinine, and blood urea nitrogen (BUN) levels. Age-matched,
untreated athymic mice were used for comparisons of hematology and chemistry data.

RESULTS

Expression and purification of WT-SAv and mutant-SAv FPs
All FPs were successfully expressed in the periplasmic space of E. coli as soluble stable
tetramers with molecular weights of ~174 KDa (Fig. 1). Expression levels for the FPs
varied, with the S45A-SAv construct producing the highest yield (358 mg/L), followed by
Y43A-SAv (144 mg/L) and WT-SAv (100 mg/L). SDS-PAGE analysis confirmed
purities of ~95% for the WT-SAv and mutant-SAv FPs after iminobiotin chromatography.
All tetrameric FP bands resolved into a single species of MW ~ 44 kDa when the FPs
were denatured by boiling before electrophoresis, consistent with a single protein entity
dissociable into a homogeneous, monomeric subunit (Fig. 1).

**In vitro characterizations of mutant-SA**<sub>v</sub> **FPs**

Flow cytometry demonstrated similar binding of the WT-SA<sub>v</sub>, S45A-SA<sub>v</sub>, and Y43A-SA<sub>v</sub>
FPs and of the parental 1F5 antibody to CD20-expressing Ramos cells (Fig. 2). In vitro
cell binding assays were then performed to compare the capture and retention of
radiolabeled biotin moieties by FPs bound to CD20 on the surface of lymphoma cells
(Fig. 3). As expected, the engineered low-affinity mutant FPs, 1F5-S45A-SA<sub>v</sub> and 1F5-
Y43A-SA<sub>v</sub>, bound significantly less radiolabeled monovalent biotin (2.9 ± 0.003 % and
4.9 ± 0.010% of the total <sup>90</sup>Y activity presented to the cells, respectively) than did the
WT-SA<sub>v</sub> FP (12.1 ± 0.02% of the <sup>90</sup>Y activity added to the cultures). S45A-SA<sub>v</sub> and
Y43A-SA<sub>v</sub> FPs were much more successful, as designed, in binding and retaining
radiolabeled divalent bis-biotin (18.1 ± 0.005% and 17.4 ± 0.001% of applied <sup>90</sup>Y activity,
respectively). By comparison, WT-SA<sub>v</sub> FP bound 25.6 ± 0.02 % of applied <sup>90</sup>Y-labeled
divalent bis-biotin. These results demonstrate that the divalent binding of the bis-biotin
ligand compensated for the lower affinity of the Y43A and S45A mutant SA<sub>v</sub> molecules,
yielding binding pairs at least comparable to the standard WT-SA<sub>v</sub> and monovalent
DOTA-biotin reagents.

**Blood clearance studies**

The blood clearances of <sup>125</sup>l-labeled mutant-SA FPs were evaluated after administration
of CAs to athymic mice fed biotin-replete normal diets. Groups of 4 mice each were
given 2.8 nmol of S45A-SA<sub>v</sub> or Y43A-SA<sub>v</sub> FP followed 20 hours later by divalent BBTG
CA, monovalent NAGB CA, or PBS (negative control). A single injection of 5.8 nmol
BBTG CA resulted in an ~ 80% decrease of circulating <sup>125</sup>l-1F5-S45A-SA<sub>v</sub> within 30
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

minutes (shown logarithmically in Fig. 4) and a ~60% decrease in $^{125}$I-1F5-Y43A-SAv (not shown). In contrast, the monovalent biotin CA, NAGB, was ineffective at clearing the low affinity $^{125}$I-1F5-S45A-SAv or $^{125}$I-1F5-Y43A-SAv FPs from the blood, with clearances not significantly different from those seen in negative control mice treated with PBS (Fig. 4). These results demonstrate that the bis-biotin BBTG CA we designed works effectively as planned for the low affinity FPs, but that the standard NAGB CA, which possesses only a single biotin moiety, is ineffective for these constructs.

**Biodistribution studies**

Biodistribution experiments were conducted in mice with 1F5-Y43A-SAv, 1F5-S45A-SAv, and 1F5-WT-SAv FPs and biotin compounds using the “dual label” method described previously. Groups of 5 athymic mice bearing Ramos xenografts were injected i.v. with 400 µg (2.8 nmol) of $^{125}$I-labeled WT-SAv, Y43A-SAv, or S45A-SAv FPs followed 20 hr later by 5.8 nmol of BBTG or NAGB CA. Four hours later, mice were injected i.v. with 1.2 nmol of $^{111}$In-DOTA-bis-biotin or $^{111}$In-DOTA-biotin. Mice were euthanized 24 hours (Fig. 5A) or 48 hours (Fig. 5B) later and $^{125}$I and $^{111}$In were measured in excised tumors and normal organs using a dual channel gamma counter, adjusting for cross-over of the two isotopes between channels. Biodistributions using the mutant-SA FPs did not include groups of mice on biotin-deficient diets since previous studies demonstrated no differences in tumor uptake between mice on biotin-deficient diets and normal diets with mutant sAv conjugates (29). There were no significant differences in tumor or normal organ biodistributions of $^{125}$I in groups given mutant-SAv or WT-SAv FPs at either 24 or 48 hours, indicating that all the anti-CD20 FPs have similar tumor targeting and tissue biodistributions (Fig. S1). Analyses of the biodistributions of $^{111}$In-labeled biotin compounds indicated that $^{111}$In-DOTA-bis-biotin was effectively targeted to tumors in mice pretargeted with mutant-SAv FPs even when mice were fed normal biotin-
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

containing diets, whereas monovalent $^{111}$In- DOTA –biotin was not effectively targeted to lymphoma xenografts with the standard WT-SAv FP unless mice were fed rigorously restricted biotin-free diets (Fig. 5). Tumors from mice pretargeted with Y43A-SAv FP followed by $^{111}$In-DOTA-bis-biotin contained 6.2 ± 1.7 % of the injected $^{111}$In per gram of tumor (%ID/gm) after 24 h compared to 5.6 ± 2.2 %ID/g with S45A-SAv but only 2.5 ± 1.6 %ID/g with WT-SAv FP (p = 0.01; Fig. 5A). The amount of radioactivity in tumors of mice treated with the mutant FP/bis-biotin systems were similar to the radioactivity in tumors excised from mice fed a biotin-deficient diet and treated with the standard WT-SAv FP and DOTA-biotin PRIT system (7.2 ± 3.2 %ID/g after 24 h, p>0.3) . Similar conclusions were derived from biodistribution studies conducted 48 hours after injection of $^{111}$In-labeled biotin compounds (Fig. 5B). Tumors excised from mice on normal diets treated with the mutant-SAv FPs followed by $^{111}$In-DOTA-bis-biotin contained 4.6 ± 1.0 %ID/g of the injected $^{111}$In- DOTA-bis-biotin with Y43A-SAv FP and 3.6 ± 1.1 %ID/g with S45A-SAv FP after 48 hours compared to 1.1 ± 0.3 %ID/g with WT-SAv FP (Fig. 6B; p < 0.0001). Tumors from mice fed a biotin-deficient diet and treated with WT-SAv FP and monovalent $^{111}$In-DOTA-biotin contained 5.2 ± 0.4 %ID/g after 48 hours. The biodistributions of $^{111}$In- DOTA-bis-biotin and $^{111}$In-DOTA-biotin in normal organs were similar in mice treated with either mutant-SAv FPs or WT-SAv FP, except that radioactivity in the blood and liver were slightly higher with mutant-SAv FPs, especially for Y43A-SAv (Fig. 5). The amount of radioactivity measured in tumors of mice fed normal diets treated with WT-SAv FP did not vary significantly whether $^{111}$In-DOTAbiotin or $^{111}$In-DOTA-bis-biotin was used, indicating that even the bis-biotin ligand was not able to displace pre-bound endogenous biotin from the biotin-binding sites of WT-SAv. Overall, the combination of mutant-SAv FPs, BBTG CA, and DOTA-bis-biotin resulted in superior biodistributions of radioactivity compared with conventional WT-SAv.
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

FP, NAGB CA, and DOTA-biotin in mice fed normal diets, where endogenous biotin levels are known to be high.

**Therapy and toxicity studies**

Therapy studies compared the efficacy of $^{90}$Y-labeled biotin compounds for treating lymphoma xenografts in mice pretargeted with the WT and mutant SAv FPs or with a non-binding negative control, CC49-WT-SAv FP (Fig. 6). Mice were assigned into 6 different groups and fed either a biotin-deficient diet or a regular biotin-containing diet. The median tumor size was $86 \pm 42 \text{ mm}^3$ at the initiation of the study with no significant differences between groups. Mice were treated with WT-SAv, S45A-SAv, Y43A-SAv, or CC49-WT-SAv FPs followed 20 hours later by either NAGB or BBTG CA. A single injection of 500 µCi $[^{90}\text{Y}]$-labeled DOTA-bis-biotin or monovalent DOTA-biotin was given 4 hours after the CA injection. Animals on a regular diet that received Y43A-SAv and S45A-SAv FPs had mean tumor volumes of $236 \pm 66 \text{ mm}^3$ and $543 \pm 320 \text{ mm}^3$ 11 days after therapy, respectively, compared to $1435 \pm 212 \text{ mm}^3$ for mice that received a non-binding control CC49-SAv FP ($p < 0.0001$) and $1129 \pm 322 \text{ mm}^3$ for animals that received WT-SAv FP ($p < 0.03$). Administration of WT-SAv FP to mice fed a biotin-deficient diet was associated with the most significant delay in tumor growth ($11 \pm 22 \text{ mm}^3$ at day 11). Treatment was well tolerated with no evidence of acute toxicity. Complete blood counts, creatinine, and transaminase levels 14 days after therapy were similar in all groups of mice except that mildly lower leukocyte counts were observed in mice in all of the treatment groups compared to control, untreated mice (Supplementary Table II).

**DISCUSSION**

The efficacy of RIT in patients with NHL has been established by a multitude of clinical trials, but the majority of patients treated with non-myeloablative doses of RIT eventually...
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

relapse (37-38). PRIT using SAv-biotin methodology has emerged as one promising approach to deliver potentially curative radiation doses to tumors while minimizing toxicities arising from the nonspecific radiation delivered to normal organs. While the high affinity of SAv for biotin is essential for this pretargeting system, this tight interaction can paradoxically present a significant limitation when naturally occurring endogenous biotin irreversibly blocks the SAv binding sites, decreases the capacity of SAv to bind radiolabeled DOTA-biotin, and reduces therapeutic efficacy. Although short-term biotin-depletion can be routinely achieved in mouse models, rigorous biotin-depletion is difficult in clinical settings due to its ubiquitous presence in all common foods. Even if endogenous biotin is successfully depleted, suboptimal targeting may still occur since the extremely slow “off rate” of radiobiotin hinders its diffusion to the center of tumor masses, due to “trapping” of radiobiotin in perivascular or peripheral locations by irreversible, high-affinity binding to the most accessible tumor cells. Computer models and experimental data have verified that such a “binding-site barrier” does exist and may compromise therapeutic efficacy of radioimmunoconjugates of extremely high binding affinities, though this problem can be at least partially overcome by administration of a large excess of Ab-SAv conjugate and radiobiotin (39-40). In this study, we demonstrate the potential advantage of a novel, engineered PRIT system utilizing mutant-SAv FPs and bivalent radiolabeled DOTA-bis-biotin for treatment of lymphomas in situations where endogenous biotin may limit the effectiveness of standard SAv-biotin PRIT. Our group has previously shown that specific delivery of high doses of radiation to tumor sites is achievable even in the presence of endogenous biotin using chemical conjugates of 1F5 Ab and mutant-SAv protein produced using heterobifunctional cross-linkers in combination with bivalent biotin ligands (28-29). Here we describe the genetic engineering, expression, in vitro characterization, and in vivo testing of novel 1F5-mutant-SAv FPs, which are more homogeneous, more amenable to scale-up, and less
costly to manufacture than the previously described Ab-mutant-SA\v chemical conjugates (33).

We have produced anti-CD20 mutant-SA\v FPs that maintain the full antigen-binding capacity of the parent monoclonal Ab, but have a reduced avidity for endogenous biotin compared to WT-SA\v FP. We selected the Y43A and S45A mutants for incorporation into scFv\v SA\v FPs from a panel of available mutants produced by site-directed mutagenesis based on prior in vitro assays, which suggested that these particular mutations would be most advantageous (27, 29). The Y43A-SA\v and S45A-SA\v mutant molecules have 67 and 907-fold lower affinity for biotin, respectively, compared to WT-SA\v, but retain robust binding to divalent biotin compounds, as demonstrated by their significantly slower off-rates for bis-biotin than biotin (27). Mutant-SA\v FPs were directly compared with WT-SA\v FP using a cell binding assay (Fig. 3), which demonstrated that both Y43A-SA\v and S45A-SA\v FPs have significantly lower affinity for monovalent biotin compared to WT-SA\v FP, but have sufficiently high affinity to efficiently capture bis-biotin ligands. These in vitro results suggest that the lower affinity of the mutant-SA\v FPs for monovalent biotin may allow pre-bound endogenous monovalent biotin to quickly dissociate, yet permit the durable capture and retention of radiolabeled divalent bis-biotin ligands by mutant-SA\v FPs. To utilize this mutant-SA\v FP and bis-biotin system effectively, a synthetic trigalactose-containing bis-biotin CA was conceptualized and generated by our group to facilitate blood clearance of the mutant-SA\v FPs (28). Pharmacokinetic experiments showed that treatment of mice with BBTG CA resulted in efficient clearance of mutant-SA\v FPs from the blood. As expected, the standard CA containing a single biotin moiety (NAGB) had a negligible effect on the blood clearance of the mutant-SA\v FPs.
Biodistribution experiments confirmed that the uptake and retention of radiolabeled DOTA-biotin by WT-SA v FP was significantly compromised at tumor sites when animals were fed a regular diet, presumably because of the deleterious impact of endogenous biotin blocking the biotin-binding sites of SAv. In marked contrast, the mutant-SA v FPs exhibited excellent tumor retention of radiolabeled DOTA-bis-biotin even in animals fed a regular biotin-rich diet. The amounts of radioactivity in normal tissues were similar in mice treated with mutant-SA v and WT-SA v FPs, except for the blood and liver, which contained slightly more radioactivity in groups treated with mutant-SA v than in mice treated with WT-SA v and NAGB CA. We presume these differences emerged because the BBTG CA was less efficient at clearing mutant-SA v FPs from the blood than the NAGB CA was at clearing WT-SA v.(17, 41) Therefore, further optimization of the bis-biotin CA is planned using variations in the galactose content of the molecule.

In therapy experiments, mutant-SA v FPs in combination with $^{90}$Y-DOTA-bis-biotin produced significant tumor growth delays in mice bearing lymphoma xenografts fed biotin-replete normal diets while the standard regimen, utilizing WT-SA v and $^{90}$Y-DOTA-biotin, had no significant effect on tumor growth in the presence of endogenous biotin. These data support the hypothesis that mutant-SA v FPs with optimized biotin-binding affinities can improve the amount of radiation delivered specifically to tumor sites compared to WT-SA v FP in the presence of competing endogenous biotin.

Although it must be acknowledged that the current gold standard combination of WT-SA FP and radiolabeled DOTA-biotin remains superior in situations where rigorous biotin depletion can be achieved, these studies demonstrate the promise of such a genetically engineered PRIT system for situations where endogenous biotin may limit its efficacy through competitive inhibition at the SAv binding site. In addition, it is conceivable that
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

the SAv mutants used in these experiments may not possess the optimal off-rates for biotin and bis-biotin to maximize tumor retention. Therefore, additional mutant-SAv FPs will be engineered and tested to further optimize the affinity and off-rate for monovalent biotin and bivalent biotin ligands.

We acknowledge that one potential limitation of SAv-biotin pretargeting systems is the immunogenicity of SAv (and of murine Ab). Although human anti-mouse Ab (HAMA) and human anti-SAv Ab (HASA) may be major limitations for applications in immunocompetent patients and for experimental regimens requiring repetitive rounds of therapy, we do not anticipate that immunogenicity will be a major limitation for this approach in patients with advanced leukemia and lymphoma, who are the focus of our investigations. We have administered RIT using murine Ab to 476 patients with non-Hodgkin lymphoma or acute myeloid leukemia at our center since 1987. Only 14 of these 476 patients (2.9%) formed HAMA between the dosimetric and therapeutic infusions of radiolabeled Ab. Furthermore, we recently opened a clinical trial of PRIT using a murine anti-CD45 Ab with SAv and radiolabeled biotin for patients with acute myeloid leukemia (ClinicalTrials.gov identifier NCT00988715; IND # 104683). No immune responses to either Ab or SAv have yet been detected in the 5 patients treated, presumably due to the compromised immune system of these patients (unpublished data). HASA have also not been major impediments in published studies of lymphoma patients treated with streptavidin-biotin PRIT by others.(19, 22) We believe that our ongoing trial, and previous PRIT studies by others, demonstrate that Ab-SA PRIT approaches are translatable to the clinic.

In summary, we have demonstrated the potential of rationally engineered mutant-SAv FPs to be used in conjunction with divalent bis-biotin CA and bis-biotin radioisotope
Pretargeted RIT using Antibody-Streptavidin Fusion Proteins

carriers to circumvent the potential blocking effects of endogenous biotin. This approach may allow the effective delivery of higher doses of radiation to tumor sites than is possible with standard SAv-biotin PRIT systems in settings where rigorous biotin depletion is not feasible.
LEGENDS FOR FIGURES

**Fig 1:** Schematization of the 1F5 scFvSAv gene and its derivative tetravalent FP.

A) The scFvSAv fusion gene is comprised of the scFv gene of the murine IgG1 anti-CD20 1F5 Ab fused to the full length SAv gene; B) a diagrammatic representation of the tetravalent FP that spontaneously forms after secretion into the periplasmic space of *E. coli*; C) Representative HPLC tracing of a purified FP (S45A-SA); SDS-PAGE analyses of unpurified and iminobiotin-purified 1F5(scFv)₄SAv WT FP (D), Y43A-SAv FP (E), and S45A-SAv FP (F), respectively. The mass of the intact FPs (174 kDa) and the monomers (44 kDa) are indicated on each SDS-PAGE gels (4-12% Tris-glycine; Invitrogen, Carlsbad, CA) stained with Coomassie blue. Lane M, migration of pre-stained molecular weight standards (SeeBlue plus; Invitrogen, Carlsbad, CA). Lane 1, loaded *E. coli* crude lysate, containing 1F5(scFv)₄SAv WT FP. Lanes 2 and 3, flow-through and wash fractions, respectively, from an iminobiotin purification column. Lanes 4 and 5, iminobiotin-purified FP without boiling (lane 4) or denatured by boiling for 5 minutes to resolve the tetramers into monomers (lane 5).

**Fig 2:** Flow cytometry showing equivalent binding of the 1F5-WT-SAv, 1F5-Y43A-SAv, and 1F5-S45A-SAv FPs to the surface of CD20-expressing Ramos cells (Fig. 2B). For comparison, binding of a non-binding negative control FP, CC49-WT-SAv (Fig 2B), a non-binding, isotype matched, negative control Ab, HB8181 (Fig. 2A) and of the parental 1F5 anti-CD20 Ab (positive control, Fig. 2A) are also shown.

**Fig 3:** Cell binding assay comparing the binding of ⁹⁰Y-DOTA-biotin and ⁹⁰Y-DOTA-bis-biotin to Ramos cells previously saturated with 1F5-WT-SAv FP, 1F5-Y43A-SAv FP, 1F5-S45A-SAv FP, or CC49-SA FP (negative control) or to untreated cells incubated...
with PBS. Ramos cells (1.0 X 10^6 per sample) were incubated with 25 µl of 20ug/ml 1F5-Y43A-SAv, 1F5-S45A-SAv, 1F5-WT-SAv, or CC49-WT-SAv FPs in a 96 round bottom ELISA plate at 4 °C for 60 minutes. Cells were then washed twice in PBS. Next, 100 ng/ml of ^{90}Y-DOTA-biotin or ^{90}Y-DOTA-bis-biotin were added to the cells and incubated at 4°C for 60 minutes. Cells were washed twice with PBS and then bound radioactivity was measured in a gamma counter.

**Fig 4:** Blood Clearance of ^{125}I-1F5-S45A-SA FP using either a monovalent biotin CA (NAGB, ◆) or a synthetic bis-biotin CA (BBTG-CA, ▲). CAs (5.8 nmol) were injected 20 hours after administration of FP, then mice were bled serially and blood radioactivity measured in a gamma counter. Control mice received 2.8 nmol of FPs without any CA ( ●). Results are expressed as the percent of the injected dose of radioactivity present per gram of blood (%ID/g) on a logarithmic scale.

**Fig 5:** Biodistributions of ^{111}In-labeled biotin compounds in tumors and normal organs of athymic mice bearing Ramos xenografts pretargeted with 1F5-S45A-SAv, 1F5-Y43A-SAv, or 1F5-WT-SAv FP. Mice were fed either normal or biotin-deficient diets for 5-6 days before injection of 2.8 nmol of FPs, as indicated. Twenty-four hours later 5.8 nmol of either monovalent NAGB CA or divalent bis-biotin CA was injected. After another 4 hours, mice were injected with 1.2 nmol of ^{111}In-labeled DOTA-biotin or ^{111}In-labeled bis-biotin. Results are shown for mice sacrificed either 24 hours (A) or 48 hours (B) after administration of the radiolabeled biotin ligands.

The graph shows the percentage of 90Y CPM bound to different fusion proteins. The x-axis represents different fusion proteins: PBS, WT, S45A, Y43A, and CC49. The y-axis represents the percentage of 90Y CPM bound, ranging from 0 to 30.

- DOTA-biotin is represented by black bars.
- DOTA-bisbiotin is represented by gray bars.

The graph indicates that DOTA-biotin and DOTA-bisbiotin have varying levels of binding to different fusion proteins, with WT showing the highest binding for both DOTA-biotin and DOTA-bisbiotin.
