**Statement of Translational Relevance (150/150 words)**

Pancreatic cancer is the fourth leading cause of cancer death in the United States. Intraductal papillary mucinous neoplasms (IPMNs) are an important precursor to pancreatic adenocarcinoma. They are commonly detected as asymptomatic lesions during abdominal scanning and pancreatic screening of individuals at high risk of developing pancreatic cancer. Most IPMNs are first detected as small lesions of low malignant potential necessitating regular imaging until their IPMN has features suggesting progression to adenocarcinoma. Molecular marker analysis of IPMNs to identify high-grade dysplasia and invasive cancer would permit optimal timing for surgical resection of IPMNs. In addition, a better understanding of molecular mechanisms that arise in pancreatic cancer precursors would improve our understanding of pancreatic cancer biology. In this study we describe the first genome-wide analysis of IPMNs and identify hundreds of aberrantly hypermethylated genes in IPMNs and identify several genes such as **BNIP3** whose hypermethylation is highly specific for high-grade IPMNs.
ABSTRACT

Purpose:

Intraductal papillary mucinous neoplasms (IPMNs) are precursors to infiltrating pancreatic ductal adenocarcinomas. Widespread epigenetic alterations are characteristic of many cancers, yet few studies have systematically analyzed epigenetic alterations of neoplastic precursors. Our goal was to perform genome-wide CpG island methylation profiling to identify aberrantly methylated loci in IPMNs.

Experimental Design:

We compared the CpG island methylation profiles of 6 IPMNs to normal primary pancreatic duct samples using methylation CpG island amplification (MCA) and Agilent CpG island microarray (MCAM) analysis. When selected 13 genes identified as differentially methylated by MCAM for methylation-specific PCR (MSP) analysis in an independent set of IPMNs and normal pancreas samples and performed expression analysis of selected genes.

Results:

We identified 2,259 loci as differentially methylated in at least one of 6 IPMNs including 245 genes hypermethylated in IPMNs with high-grade dysplasia compared to normal pancreatic duct samples. Eleven of 13 genes evaluated by MSP were more commonly methylated in 61 IPMNs than in 43 normal pancreas samples. Several genes, \( \text{BNIP3} \), \( \text{PTCHD2} \), \( \text{SOX17} \), \( \text{NXPH1} \), \( \text{EBF3} \), were significantly more likely to be methylated in IPMNs with high-grade than with lower-grade dysplasia. One gene, \( \text{Sox17} \), demonstrated loss of protein expression by immunohistochemistry in 22% (19 of 88) of IPMNs. The most specific marker, \( \text{BNIP3} \), was not methylated in any IPMNs with low-grade dysplasia or in normal pancreas samples.
Conclusions:

IPMNs undergo extensive aberrant CpG island hypermethylation. The detection of genes selectively methylated in high-grade IPMNs such as BNIP3 may have utility in the clinical evaluation of IPMNs.

INTRODUCTION

Pancreatic cancer is the 4th leading cause of cancer death in the United States. In 2011, it is estimated that 44,030 Americans will be diagnosed and 37,660 patients will die of pancreatic cancer (1). The 5-year survival for patients with all stages of infiltrating pancreatic ductal adenocarcinomas is only ~6% and is only ~23% for patients whose disease is detected early enough to undergo surgical resection with curative intent (1). Detecting early-stage pancreatic cancer and its precursors by screening high risk individuals is currently considered the best way to improve patient survival (2, 3). Intraductal papillary mucinous neoplasms (IPMNs) arise in the pancreatic ductal system and are distinct mucin-producing cystic precursor lesions of pancreatic ductal adenocarcinomas. IPMNs are large enough (usually more than 1 cm) to be detected by clinical imaging tests (4), unlike pancreatic intraepithelial neoplasias (PanINs), which are lesions of <5 mm (5). With the increasing use of abdominal imaging, IPMNs are commonly detected as incidental lesions(6).

Many of the molecular alterations of pancreatic ductal adenocarcinomas (reviewed in (7)) have been identified in IPMNs (8-10). Thus, the prevalence of KRAS2 mutations increases in parallel with degree of dysplasia of IPMNs, and have been detected in ~80% and TP53 mutations in ~50% of IPMNs (11) with high-grade dysplasia. In addition, somatic mutations of the STK11/LKB1 (12) and PIK3CA genes (13) have been identified in ~10% of IPMNs. A low prevalence of chromosomal losses have also been identified in IPMNs (14). Compared with PanINs and pancreatic ductal adenocarcinomas, IPMNs rarely show inactivation of DPC4/SMAD4 even in high-grade lesions (15, 16).

While genome-wide analyses of aberrant DNA methylation of pancreatic ductal adenocarcinomas have been described (17-21), no such DNA methylation analyses have been reported for IPMNs. Candidate gene analysis of genes methylated in pancreatic and other cancers has been performed in IPMNs revealing that several genes including
CDKN1C/p57KIP2, CDKN2A/p16, PENK, SOCS-1, RELN, TFPI2, SPARC, and others undergo aberrant methylation often associated with gene silencing (18, 20, 22-25).

Genome-wide DNA methylation analysis of IPMNs has the potential not only to identify genes targeted in IPMNs but also provide a better understanding of the timing of aberrant methylation events during pancreatic tumorigenesis, thereby helping to elucidate the DNA methylation events important for tumor development. In this study, we utilized Methylated CpG island Amplification coupled with genome-wide CpG island microarrays (MCAM) followed by validation by methylation specific PCR (MSP) to identify differentially methylated genes in IPMNs.
METHODS

An overview of the experimental approach that we used in this study is summarized on Figure 1.

Cell Lines

Fourteen human pancreatic cancer cell lines, including A32-1, A38-5, BxPC3, Capan1, Capan2, CFPAC1, FamPanc, Miapaca2, Panc-1, Panc1.28, Panc2.5, PL4, PL8, and Su8686, were also used. An immortalized cell line derived from normal human pancreatic ductal epithelium (HPDE) was generously provided by Dr. Ming-Sound Tsao (University of Toronto, Canada).

Patients and Tissues

Tissues were obtained for methylation analysis and immunohistochemistry and from patients with IPMNs as well as from patients with pancreatic ductal adenocarcinoma and from disease controls. A summary of the demographics of the patients and their tissues used in this study is provided in Table 1 and Supplemental Table 1. Fresh-frozen sections from 61 IPMNs and 10 invasive ductal adenocarcinomas with an associated IPMN were collected from 71 patients who underwent surgical resection of their neoplasm at the Johns Hopkins Medical Institutions from 1999 to 2008. These patient samples were selected based on the availability of stored tissues with sufficient numbers of neoplastic cells for DNA methylation analysis. Fresh-frozen normal pancreatic tissues were obtained from 35 patients with ductal neoplasms (5 with IPMNs and 30 with an associated invasive pancreatic ductal adenocarcinomas), and 8 patients with benign pancreatic neuroendocrine neoplasms and used as control samples. Hematoxylin and eosin staining of frozen sections was performed to assess the degree of dysplasia using criteria described elsewhere (26-29). The IPMNs were classified by their grade of dysplasia using the new WHO classification into either low-, intermediate-, or high-grade dysplasia (30). IPMNs
were also classified by their histologic subtype and localization of each IPMN as described elsewhere (27).

Formalin-fixed paraffin-embedded IPMN tissues were additionally retrieved from 88 patients, 75 of these cases were used to create tissue microarrays for immunohistochemical labeling. In addition, tissue microarrays of formalin-fixed paraffin embedded pancreatic ductal adenocarcinoma tissues from 111 patients who underwent surgical resection of the pancreas at our institution were also analyzed by immunohistochemistry. All specimens were collected and analyzed with the approval of the Johns Hopkins Committee for Clinical Investigation.

IPMNs were carefully manually microdissected from frozen sections to collect neoplastic cells. Normal pancreatic ductal epithelial cells were selectively microdissected from frozen sections adjacent to IPMN, pancreatic ductal adenocarcinoma, or well-differentiated pancreatic neuroendocrine tumors using the PALM micro laser system (Carl Zeiss microimaging Inc., North America, Thornwood, NY).

DNA Extraction

Genomic DNA was extracted from the microdissected samples with QIAamp DNA Micro Kit (Qiagen, Inc., Valencia, CA) following the manufacturer's protocol. Extracted DNA was quantified by either Quantifiler (Applied Biosystems, Foster City, CA) or PicoGreen Assay (Invitrogen, Carlsbad, CA).

Methylated CpG island Amplification (MCA)

MCA was performed on DNA from 6 IPMNs (1 IPMN with low-grade, 3 intermediate-grade, and 2 with high-grade dysplasia) and DNA from matched normal pancreatic samples as previously
described with minor modifications (31). In brief, 500 nanograms of DNA was digested with
\textit{SmaI} and \textit{XmaI} (New England Biolabs, Inc., Ipswich, MA). Unmethylated \textit{SmaI} sites are
eliminated by \textit{SmaI} digestion, which leaves a blunt end fragment. In contrast, CCCGGG sites
with methylated CpG are not cut by \textit{SmaI}. These methylated \textit{SmaI} sites can then be digested
with \textit{XmaI}, which is the non-methylation-sensitive \textit{SmaI} isoschizomer, leaving a CCGG
overhanging sticky end. Adaptors are ligated to these sticky ends, and PCR is performed to
amplify the methylated sequences. Restriction fragments were ligated to an RMCA adaptor and
amplified by PCR in a 100 µl volume containing 200 pmol of RMCA 24-mer primer, 600 mM
Tirs-SO_4, 2mM MgSO_4, 160 mM (NH_4)_2SO_4, 200 µM each dNTP, 2% v/v DMSO, 0.5 M betaine
and 2 U of Platinum Taq Hifidelity polymerase (Invitrogen). The reaction mixture was incubated
at 72°C for 5 min and at 95 °C for 3 min, and then subjected to 25 cycles of 1 min at 95 °C and
3 min at 77 °C followed by a final extension of 10 min at 77 °C.

\textbf{Agilent 244K human promoter and CpG island microarrays}

Agilent’s 244K Human promoter chip-on-chip microarray contains 195 K CpG island probes and
50 K non-CpG island probes and interrogates 27,800 CpG islands covering 21MB with an
average of 8 probes per island. Array hybridization was performed by the Sidney Kimmel
Cancer Center Microarray Core Facility at Johns Hopkins. Briefly, 2 µg of MCA amplicon was
labeled with either Cy3-dUTP or Cy5-dUTP (Perkin Elmer, Waltham, MA) by using BioPrime
DNA Labeling System (Invitrogen). These dye-labeled amplicons were then mixed and co-
hybridized to each of the 244K human promoter Chip on-chip microarrays. After the
hybridization, the microarray slides were washed, dried and scanned using an Agilent G2505B
scanner.
Data were extracted with Agilent Feature Extraction 9.1 software. Methylation-specific sites were called with Agilent Genomic Workbench Standard Edition 5.0.14 software for methylation (CH3) analysis, which calculates the normalized log2-signal ratios (NLR) and combined Z-scores for each probe. The cut-off of 4-fold differential methylation [normalized log2 signal ratio (NLR) >2 or <-2] which was validated previously (31), was used in order to identify differentially methylated probes in IPMN DNA relative to normal pancreatic duct DNA.

Methylated gene patterns were analyzed for evidence of associated Gene network and pathway analysis using Ingenuity Pathways Analysis (Ingenuity systems, Redwood City, CA; http://www.ingenuity.com) software.

Bisulfite Treatment of DNA

Microdissected DNA was treated by sodium bisulfite (Sigma, St. Louis, MO) for 3 hours at 50°C as previously described (32). The bisulfite DNA was purified with Wizard DNA clean up system (Promega, Madison, WI).

Bisulfite sequencing

The methylation status of the 5' CpG islands of PCDH17 and SOX17 was determined by bisulfite sequencing as described previously (31). Thirty nanograms (ng) of bisulfite-treated DNA in 3 µl was amplified by PCR with RDA buffer. PCR conditions were as follows: (a) 95°C for 5 min; (b) 45 cycles of 95°C for 20 s, 62°C for 20 s and 72°C for 30 s; and (c) a final extension of 4 min at 72°C. Amplicons were purified with the QIAquick PCR purification kit (Qiagen, Germantown, MD). Sequence analysis was carried out at the Synthesis and Sequencing Facility at Johns Hopkins University using a 3730xl DNA Analyzer (Applied Biosystems). PCR primer sequences for PCDH17 and SOX17 genes are summarized on Supplemental Table 2.
Methylation Specific PCR (MSP)

MSP was performed as previously described using 10 ng of input DNA for each MSP reaction (25). Primer sequences for the 11 genes identified as differentially methylated are provided in Supplemental Table 2.

5-aza-2′-deoxycytidine Treatment

Cell lines were treated with 1 μmol/L of 5-aza-2′-deoxycytidine (5-aza-dC; Sigma) for 4 days as we described previously (17).

RNA Isolation and Real Time-PCR

Total RNA was extracted using the mirVana miRNA Isolation Kit (Ambion) and reverse transcribed using Superscript III Reverse Transcriptase and oligodT (Invitrogen) for quantitative reverse transcriptase-PCR (RT-PCR) following the manufacturer’s protocol. cDNAs for SOX17 and EBF3 were quantified with SYBR Green PCR Master Mix (Applied Biosystems). PCR was performed with a StepOnePlus Real time PCR system (Applied Biosystems). GAPDH was used as a reference for SYBR Green. Relative expression was determined with the ΔΔCt method. The primer sequences and PCR conditions are summarized on Supplemental Table 2.

Immunohistochemistry

Immunohistochemistry was performed as previously described on 88 IPMNs, including 75 IPMNs on tissue microarrays and 13 IPMNs on conventional slides, and 111 pancreatic ductal adenocarcinomas on tissue microarrays. The antigen retrieval step was carried out in a steam
pressure cooker containing preheated high pH antigen retrieval buffer (DakoCytomation, Glostrup, Denmark) at 95°C for 20 min. To minimize non-specific antibody binding, sections were incubated with protein blocker (DakoCytomation) for 10 min, and stained using the LSAB Detection method (DAKO, Carpinteria, CA). Primary anti-Sox17 (GT15094, anti-goat antibody, Neuromics Antibodies, Edina, MN, 1:400 dilution) monoclonal antibodies was applied manually to the sections and incubated for 30 min at room temperature. The remaining steps were performed using an automated immunostainer (DakoCytomation). Immunolabeled sections were lightly counterstained in with hematoxylin, dehydrated in ethanol, and cleared in xylene. Immunohistochemical labeling of sox17 protein was scored using a previously described histologic score quantifying both the area and intensity of labeling (33). Labeling Intensity was designated as 0–2 for absent, weak, and strong, and the area of labeling was designated as 0–4 for <5%, 5–25%, 26–50%, 51-75, and >76%, respectively (33). Sox17 expression was classified as reduced when <50% of tumor cells were labeled.

**Statistical Analysis**

The mean number of methylated genes was in subtypes of IPMN were compared by Student T-test and Mann-Whitney U-test. The proportion of genes methylated in each group was compared by ANOVA and post-hoc Duncan's tests. Associations between categorical variables were examined with Pearson’s chi-square and Fisher’s exact tests. Linear regression analysis was performed to examine the relationship between patients’ age and the number of methylated genes. Statistical analyses were performed with SPSS version 17 (IBM SPSS, Somers, NY, USA). A P-value < 0.05 was considered statistically significant.
RESULTS

Characteristics of Cases

The 6 patients whose IPMNs were analyzed by MCA microarrays included 3 males and 3 females, their mean age was 65.8±11.9 years (range 48 to 79 years). One patient had an IPMN with low-grade dysplasia (6T), 3 had IPMNs with intermediate-grade dysplasia (2T, 55T, 60T), and 2 had IPMNs with high-grade dysplasia (4T, 11T). The pooled normal pancreatic duct samples were obtained from 3 of these patients (2T, 4T, and 6T).

Identification of differentially methylated loci between IPMN and normal pancreatic ducts

Six MCA experiments were performed using the Agilent 244K CpG island microarrays with each MCA experiment comparing an IPMN to pooled laser-captured microdissected normal pancreatic duct samples. A≥4-fold differential methylation [normalized log₂ signal ratio (NLR) >2 or <-2] in the IPMNs relative to the normal pancreas was used in order to identify differentially methylated probes. This cut-off was validated using bisulfite sequencing (31). Based on this criterion, the number of probes and genes differentially methylated in each paired IPMN/normal pancreatic duct sample was 1338 probes/ 745 genes (6T, low-grade dysplasia); 893 probes/ 515 genes (2T, intermediate-grade dysplasia); 1204 probes/ 726 genes (55T, intermediate-grade); 1158 probes/ 688 genes (60T, intermediate-grade dysplasia) 1295 probes/ 710 genes (4T, high-grade dysplasia); 8449 probes, 5091 genes (11T, high-grade dysplasia). Overall, there were 10,323 uniquely hypermethylated probes in at least one of the 6 IPMN/normal pancreatic duct pairs representing 2,195 loci and 2,244 genes (Supplemental Table 3).

To identify more commonly hypermethylated genes, we determined the probes and genes hypermethylated in 2 or more of the 6 IPMNs evaluated by MCA microarray analysis. The
resulting list included 2,406 hypermethylated probes representing 692 loci and 708 genes (Supplemental Table 4).

Understanding the molecular events associated with high-grade IPMN neoplasia is particularly important not only because of their potential biological importance but also because IPMNs with high-grade dysplasia (high-grade IPMNs) warrant surgical resection and markers of high-grade IPMNs could have diagnostic utility. We therefore identified probes differentially methylated in the 2 high-grade IPMNs compared to normal pancreatic duct samples. This comparison yielded 840 probes, corresponding to 245 genes (Supplemental Table 5). Of these 245 hypermethylated genes, 53 genes were only hypermethylated in both of the high-grade IPMNs (Supplemental Table 6).

Many on this list of 245 hypermethylated genes have been identified as aberrantly methylated in ductal adenocarcinomas of the pancreas, including ADCYAP1, ALK, CCNA1, EYA4, GALR1, LHX1, LHX2, LIN28, MYOD1, MDFI, NPY, NRN1, NRXN1, PAX1, PENK, PITX2, TFPI2, SALL3, SLIT2, SOX17, TLX3, and ZNF415 (17, 18, 20, 31, 34). We also confirmed our previous findings of aberrant methylation of the genes TFPI2, SARP2/SFRP1, PENK, and CLDN5 in a subset of IPMNs (24, 25). The genes, DLX1, EVX2, and TBX18, have been reported to be abnormally hypermethylated in other cancers (Supplemental Table 7).

Some important genes were methylated in only one of the IPMNs including CDKN2A/p16 (Supplemental Table 2). Several genes methylated in <10% of pancreatic cancers such as CDH1/e-cadherin and hMLH1 (23, 24) were not identified as methylated in any of the IPMNs.

**Differentially Hypermethylated Genes in IPMNs vs. Pancreatic Cancers**
We compared the number of differentially methylated genes in IPMNs to those of pancreatic cancers obtained using the same MCAM strategy utilized to profile IPMNs (35). The median number of probes methylated in the IPMNs was 1249.5 and for pancreatic cancer it was 7713 (p=0.018, Mann-Whitney U test). The median number of hypermethylated genes in IPMNs relative to normal pancreatic duct (506±1804.0 genes) was significantly lower than in 9 pancreatic cancers relative to normal pancreatic duct (2285.7±608.2 genes) (P=0.04).

**Validation of hypermethylated genes by MCA microarray analysis**

To confirm the accuracy of our MCA microarray data, we utilized MSP to evaluate the methylation status of 13 genes in an independent set of 61 IPMNs and 43 normal pancreas samples. Genes that were selected had multiple probes identified as differentially methylated by MCAM. These genes were analyzed in an independent set of IPMNs and normal pancreas samples. This analysis was limited to 13 genes because the amount of available DNA from our tumor samples available for these assays after bisulfite-modification was limited. Indeed, three of the genes were tested in a smaller set of IPMNs and normal pancreas samples (BNIP3, PTCHD2, LIN28) because of limited sample availability. Most of these genes, including BNIP3, PTCHD2, LIN28, NXPH1, SOX17, EBF3, PAX6, FOXF2, PCDH17, and SALL3, were identified as methylated by MCAM analysis in the high-grade IPMNs. Representative images of results of MSP are depicted in **Supplemental Figure 1**. The demographic and clinicopathological information of the 65 patients whose IPMNs were studied is summarized on **Table 1** and **Supplemental Table 1**. Two of 6 IPMN samples used for MCA microarray were included in the validation, one an IPMN with low-grade dysplasia, and the other an IPMN with intermediate dysplasia and the results of MSP and MCAM were 100% concordant in these 2 samples.
Overall, the genes tested for methylation by MSP analysis confirmed the results of the MCAM array analysis, showing that the majority of genes tested were commonly methylated in the IPMNs, compared to much lower prevalence of methylation in normal pancreas (<10% of samples for most genes evaluated). Two of the 13 genes tested (IRX2 and HoxA5) were not identified as differentially methylated in IPMNs relative to normal pancreatic duct samples by MSP (methylated DNA was as prevalent in normal as in IPMN samples).

By MSP analysis, significantly more genes were methylated in IPMNs than in normal pancreata and higher grade IPMNs had more methylated genes than lower-grade IPMNs. Thus, 48.4±21.9% of genes were methylated in IPMNs with low-grade dysplasia, 52.2±24.2% in IPMNs with intermediate-grade dysplasia, 73.9±20.9% in IPMNs with high-grade dysplasia, and 85.1±18.5% in IPMNs with an associated invasive adenocarcinoma (P<0.0001, ANOVA; Supplemental Figure 2). More genes were methylated in IPMNs with high-grade dysplasia or with associated invasive adenocarcinoma than IPMNs with low-grade dysplasia or with intermediate-grade dysplasia (P<0.05, post-hoc Duncan test). And more genes were methylated in IPMNs with low-grade dysplasia or IPMNs with intermediate-grade dysplasia than in normal pancreata (P<0.05, post-hoc Duncan test). These results are summarized in Table 2 and Supplemental Figure 2. These results are consistent with our previous investigations of IPMN methylation investigating candidate genes that had been identified as aberrantly methylated in pancreatic ductal adenocarcinomas (25, 36). In this previous study, we also found an overall trend for a higher prevalence of aberrant methylation in higher grade IPMNs, but this was limited to some genes (e.g. TFPI-2, TSLC1, SARP2, UCHL1, CLDN5), whereas for other genes, aberrant methylation is common even low-grade IPMNs (SPARC, RELN).

Since IPMNs can be subclassified by their anatomic localization and their histological subtype, we compared DNA methylation profiles within these subgroups. The percentage of genes methylated in main-duct IPMNs (71.3±23.8%) was significantly higher than those in
branch-duct type (44.4±20.0%, P<0.0001). Main-duct IPMNs are more likely to be associated with high-grade lesions and invasive adenocarcinomas, and once histologic grade is taken into account, the relationship between the number and pattern of methylated genes with IPMN location was no longer significant. IPMNs also can be subclassified by their histological phenotypes into pancreatobiliary, intestinal and gastric subtypes. We found that the percentage of genes methylated in pancreatobiliary type IPMNs (72.8±22.6) was significantly higher than gastric type IPMN (51.2±22.5, P=0.001, Student-T test), but not after adjusting for grade of IPMN. Similarly, there was a borderline difference in the percentage of genes methylated in gastric vs. intestinal-type IPMNs (64.9±26.5)(P=0.08), but this difference was also not significant after adjusting for neoplastic grade.

The number of genes methylated in normal pancreatic tissues from patients with ductal neoplasms was marginally but not significantly higher than in those from patients with well-differentiated pancreatic endocrine neoplasms (13.0±13.9 vs. 4.7±9.3%, p=0.08, Mann-Whitney U-test) which could be related to patient age as the mean age of patients with ductal neoplasia (65±12 years) was significantly higher than those with well-differentiated pancreatic endocrine neoplasms (53±13 years, P=0.02, Mann-Whitney U-test). Among patients with IPMNs, we found a significant correlation between patient age and the number of methylated genes in their IPMN (P<0.001, R=0.34, Linear regression analysis). There was no evidence that this was related to IPMN grade as there was no significant difference in patient age by IPMN grade in our study population. These results are similar to our previous analysis of methylation in pancreatic samples (25) where with a different panel of genes we observed a small but significantly higher number of methylated genes in the normal pancreata of patients with ductal neoplasms compared to patients with neuroendocrine tumors (25).

We next compared the progression of individual gene methylation by neoplastic grade. Aberrant hypermethylation of BNIP3 was more common in IPMNs with high-grade dysplasia.
(57%, 8/14 cases) than those with intermediate- (20%, 3/15 cases, P=0.06), or low-grade
dysplasia (0%, 0/8 cases, P=0.02) and more common than in normal pancreas samples (0%,
0/18 cases, P<0.001). Similarly, PTCHD2 methylation was also significantly more common in
IPMNs with high-grade dysplasia (50%, 7/14 cases) than those with low- grade dysplasia (0%,
0/8 cases, P=0.02) or normal pancreas (6%, 1/18 cases, P=0.001). PTCHD2 methylation is also
detected in a smaller percentage of IPMNs with intermediate-grade dysplasia (27%, 3/11 cases).
There was also evidence of increasing methylation of EBF3 (P=0.01; chi-square test), SOX17
(P=0.01), and NXPH1 (P=0.001) by neoplastic grade, but not for any of the other genes
analyzed, PAX6 (P=0.16), SALL1 (P=0.68), FOXF2 (P=0.13), SALL3 (P=0.14) or PCDH17
(P=0.13). The presence of methylation in at least one of the two markers most specifically
associated with high-grade dysplasia (BNIP3 and PTCHD2) had a sensitivity of 71% (10/14).

SOX17 Expression Analysis

To evaluate the expression of one of the aberrantly methylated genes in IPMNs, we
selected SOX17, a gene with an available antibody to its protein product. (There were no
commercially antibodies available that had been shown to work for immunohistochemistry to the
protein products of other genes we analyzed by MSP). We next examined the expression of the
protein product of one of the genes commonly methylated in IPMNs by immunohistochemistry.
Among 88 resected primary IPMNs (see Figure 2 for representative images), Sox17 protein
expression was significantly lower in IPMNs than in associated normal pancreatic duct
(histologic score 3.0±2.2vs. 7.8±0.7, Student T-test, p<0.001). Sox17 expression was absent in
27% (4/15) of low-grade IPMNs, 21% (6/29) of intermediate-grade IPMNs, and 20% (9/44) of
high-grade IPMNs. Reduced expression of sox17 was observed in 60% (9/15) of low-grade
IPMNs, 69% (20/29) of intermediate-grade IPMNs, and 75% (33/44) of high-grade IPMNs. Loss
of Sox17 expression in IPMNs was not associated with clinicopathologic factors, such as histologic subtype, grade and tumor location. We also observed complete loss of Sox17 in a similar proportion of pancreatic ductal adenocarcinomas (29%, 32/111).

We also found evidence for epigenetic regulation of Sox17 expression in pancreatic cancer cells. SOX17 RNA was upregulated in several pancreatic cancer cell lines, including A32-1, Capan1, FamPanc, and Panc2.5 after 5-aza-dC treatment (Supplemental Figure 3). We also performed bisulfite sequencing of SOX17 in pancreatic cancer cell lines and found methylation of most of the CpGs in the 5' region of SOX17 in 6 pancreatic cancer cell lines tested, and it was predominantly unmethylated in 6 normal pancreatic samples, and the non-neoplastic cell line, HPDE (Supplemental Figure 4). Similarly, 5' CpGs of PCDH17 were predominantly methylated in 11 pancreatic cancer samples, and predominantly unmethylated in 5 of 8 normal pancreatic tissue samples (Supplemental Figure 5).
Discussion

In this study we find that the pancreatic precursor neoplasms known as IPMNs are characterized by widespread aberrant hypermethylation affecting several hundred CpG islands. Extensive aberrant hypermethylation has been demonstrated in pancreatic and other invasive cancers, but the timing of such aberrant methylation during tumor development has not been well established. In our study we find that even low-grade IPMNs harbor aberrant methylation of hundreds of CpG islands, with evidence of increased levels of methylation with increasing neoplastic grade. Consistent with this trend is the finding that significantly more genes are methylated in pancreatic ductal adenocarcinomas than in IPMNs.

Among the genes tested, both BNIP3 and PTCHD2 had promising performance characteristics as diagnostic markers of IPMNs with high-grade dysplasia. Aberrant methylation of BNIP3 has been described in pancreatic ductal adenocarcinomas, but not in IPMNs (37). PTCHD2/DISP3 is a trans-membrane protein and shares a PTCH/DISP homologous domain and aberrant methylation of PTCHD2/DISP3 has not been described in any solid cancer.

Our MCAM analysis identified other genes that were selectively methylated in high-grade IPMNs including the gene TFPI-2 which we have previously described as much more commonly methylated in high-grade IPMNs and infiltrating adenocarcinomas than in low- or intermediate-grade of IPMNs (25). Since most IPMNs are detected incidentally when they are small neoplasms of low malignant potential, they are managed by surveillance and only undergo resection when there is a concern for high-grade neoplasia or malignancy. Since imaging tests cannot differentiate low-grade from high-grade neoplastic lesions, markers that can reliably identify the grade of neoplasia in IPMNs could help determine the optimal timing of resection for patients undergoing surveillance (38). Genes with methylation profiles highly specific for high-
grade dysplasia in IPMNs could be useful as markers for detection in fine needle aspirates of IPMN samples (3, 38-40).

Of the 2244 genes identified as aberrantly methylated in any IPMN, many have been identified as aberrantly methylated in pancreatic cancers, including genes bound by polycomb and those involving pathways and gene families commonly targeted in pancreatic ductal adenocarcinomas. For example, of the 331 aberrantly methylated genes involved in transcription regulation, many were members of the homeobox superfamily. Indeed, 41 of the 245 aberrantly methylated genes in high-grade IPMNs were homeobox genes. Homeobox genes encode transcription factors and play a key role in development by activating or repressing down-stream target genes involved in many cellular processes, including adhesion, apoptosis, body patterning, differentiation, migration, proliferation, polarity and proliferation and are commonly observed in cancers (41).

Several members of the Wnt signaling pathway were also found to be hypermethylated in IPMNs by MCAM analysis including multiple genes previously shown to be epigenetically silenced both in invasive pancreatic and other types of cancer such as FZD10, SFRP1, APC2, SOX11 and SOX17. SOX17 is expressed in the developing pancreas and has an important role in endoderm development (42). Sox17 represses the Wnt/β-catenin signaling pathway (43) and its silencing has been reported in colorectal and stomach cancers (43, 44). We and others have previously described aberrant hypermethylation of SOX17 in pancreatic cancers (31, 34). In the present study, we find that aberrant hypermethylation of SOX17 and silencing of its protein product is evident early during pancreatic neoplastic development and the prevalence of methylation increases with IPMN grade, and this was associated with silencing of SOX17 expression in ~1/4 of IPMNs and pancreatic ductal adenocarcinomas.
Another gene we found to be commonly methylated in IPMNs was the putative tumor suppressor gene *EBF3/COE3* which encodes a transcription factor involved in regulating differentiation and neurogenesis (45). Although aberrant methylation of *EBF3* has not been reported in pancreatic neoplasms previously, such methylation has been reported in several cancers, including glioblastoma and head and neck squamous cell carcinomas (45, 46). Furthermore, *EBF3* mutation has been described (47). Methylation of *EBF3* by MSP was detected in only 1 of 40 normal pancreas tissues.

Many genes involved in cell adhesion were also hypermethylated in IPMNs, including members of the cadherin superfamily *CDH2, CDH4, PCDH7, PCDH8, PCDH10, PCDH17, and PCDHB7*. Loss of the protein product of *CDH2* (n-cadherin) expression has been reported in infiltrating pancreatic ductal adenocarcinomas (48). We and others have previously reported occasional silencing, mutation and focal loss of expression of *CDH1/E-cadherin* in pancreatic cancers (49, 50). Interestingly, occasional somatic mutations of cadherins and protocadherins have been identified in pancreatic cancers (47).

In summary, genome-wide CpG island methylation profiling of IPMNs reveals that IPMNs harbor aberrant methylation of hundreds of CpG islands relative to normal pancreatic duct and that aberrant CpG island methylation increases with IPMN grade. The specificity of methylation of genes such as BNIP3 for high-grade dysplasia highlights the potential diagnostic applications of methylated genes in the evaluation of IPMNs.

**Figure 2.** Immunohistochemical analysis of Sox17 protein expression of IPMNs (A) Sox17 labeling in normal pancreatic ductal epithelial cells and acinar cells (x20). Lack of tumoral sox17 expression in (B) an IPMN with low-grade dysplasia (x10), (C-D) an IPMN with intermediate-grade dysplasia (x20), and (E) an IPMN with high-grade dysplasia (x20). (F) An IPMN with high-grade dysplasia expressing sox17. Stromal fibroblasts expressed sox17.
Methylated CpG island amplification (MCA) array analysis of IPMN

Performing MCA array of promoters of IPMN and normal pancreas (Agilent 244K array)

Data analysis (Agilent Genomic Workbench)

- 2,244 hypermethylated genes in any IPMNs
- 708 hypermethylated genes overlapped in more than 2 IPMNs
- 245 hypermethylated genes in IPMNs with high-grade dysplasia

Validation of MCA array data

1. Bisulfite sequencing
2. Methylation specific PCR
3. Immunohistochemistry
4. Real time-PCR after 5-aza-dC treatment
