Running Title:
Molecular Advances in Pediatric LGG

Conflict of Interest: Dr. Kieran is an advisor for Boehringer-Ingelheim, Incyte, Merck, Novartis and Sanofi.

Funding or Grants: St. Baldrick’s Scholar (ER); Pediatric Low-Grade Astrocytoma Foundation (ER; MWK), Andrysiak Low-Grade Glioma Scholar Award (MWK), Solving Kid’s Cancer (KJC).
ABSTRACT

Pediatric low-grade gliomas (pLGG) account for more brain tumors in children than any other histologic subtype. While surgery, chemotherapy and radiation remain the mainstay of upfront treatment, recent advances in molecular interrogation of pLGG have demonstrated a small number of recurring genetic mutations in these tumors that might be exploited therapeutically. Notable findings include abnormalities in the RAS/MAP kinase pathway such as NF-1 loss or BRAF activation, and mTOR activation. Recent identification of activating re-arrangements in c-MYB and MYBL1 in pediatric diffuse astrocytoma also provide candidates for therapeutic intervention. Targeting these molecularly identified pathways may allow for improved outcomes for patients as pediatric oncology moves into the era of biology-driven medicine.
BACKGROUND

Pediatric gliomas include multiple histologies including astrocytomas, ependymomas, and oligodendrogliomas. Pediatric low grade gliomas (pLGG) are the most common pediatric brain tumors, and this review will focus on the emerging translational science related to these tumor types.

Pediatric astrocytic tumors are currently divided by the World Health Organization (WHO) into numerous subtypes (Table 1). pLGG include WHO Grade 1 and 2 tumors with pilocytic astrocytomas (PA) predominating. Although most pLGG carry a favorable prognosis, a significant minority are more aggressive (1). Surgical resection can be curative, but this is often not feasible due to the tendency of these tumors to present in midline locations including the diencephalon and brain stem (2). Radiation therapy can be utilized in the adjuvant setting for recurrent or progressive tumors. Unfortunately, there can be significant long-term morbidity including impaired cognition, vasculopathy, endocrinopathies and secondary tumors (3). Chemotherapy, which was presumed to be less efficacious in the treatment of LGG given the relatively slow growth rate of these tumors, was initially reluctantly utilized when surgical and radiation options had been exhausted. However, responses were seen in both the upfront and recurrence setting, generating interest in the use of chemotherapy to avoid, or delay, radiation therapy. Numerous regimens have been developed including carboplatin/vincristine (4, 5), TPCV (thioguanine/procarbazine/CCNU, vincristine) (6), carboplatin alone (7), oral temozolomide (8), vinblastine (9), cisplatin/etoposide (10) and others. In general, regardless of regimen, a minority of children will have a measurable reduction in the size of the tumor, many will have stable disease, and the remainder will progress during or after completion of treatment. Progression-free survival for most chemotherapeutic regimens tested is typically in the 30-40% range at 5 years. A recent large randomized Children’s Oncology Group trial showed that TPCV trended towards slightly better efficacy for patients with LGG than carboplatin/vincristine (CV) (11).
Diagnosis of a pLGG is generally based on imaging features and, when the tumor is biopsied or resected, histopathologic interpretation. Challenges abound in the classification of LGG in children with many tumors appearing to be a mix of histologic subtypes confounding classification. Molecular diagnostics have only recently begun to be incorporated into the initial evaluation of pLGG. One of the first applications of the knowledge gained from molecular profiling of tumors was the use of the mammalian target of rapamycin (mTOR) inhibitor everolimus in the treatment of children with tuberous sclerosis (TSC) who frequently develop subependymal giant cell astrocytomas (SEGA). Most patients with TSC harbor a mutation in either the \textit{TSC1} (hamartin) or \textit{TSC2} (tuberin) gene; either mutation leads to overactivation of mTOR. Everolimus administration resulted in appreciable tumor reduction and an associated decrease in the frequency of seizures seen in these patients (12, 13).

**ON THE HORIZON**

**Targeting the RAS/MAP kinase pathway:**

Nearly all pLGGs have alterations in the RAS/MAP kinase pathway (Figure 1) (14-16). Constitutive activation of this pathway can be due to loss of neurofibromin (NF1), a RAS GTPase activating protein (17, 18). In non-NF1 associated LGG, the most common alteration is a fusion and tandem duplication of BRAF with KIAA1549, a protein of unknown function (19, 20). This fusion deletes the regulatory domain of BRAF and deletes most of KIAA1549, leaving a rump of KIAA1549 and a constitutively active BRAF (14-16). A smaller percentage of LGG harbor the \textit{BRAF}^{V600E} mutation (21) that is a hallmark of cutaneous melanoma (22). Another subset harbors fibroblast growth factor receptor (FGFR) alterations leading to constitutive activation of the MAP kinase and mTOR pathways (23). Interestingly a group of predominately diffuse low grade astrocytomas have activating alterations of the \textit{MYB} or \textit{MYBL1} transcription factors (23, 24). These tumors also have MAP kinase activation equivalent to that observed in BRAF-driven tumors, suggesting that MAP kinase signaling may be a common driver pathway in pLGG. High-level activation of the MAP kinase pathway is associated with oncogene-induced
senescence in many neoplasms, and the most aggressive pLGGs have deletion or silencing of the p16<sup>INK4a</sup> locus, allowing them to by-pass this anti-tumor mechanism (25-27).

The presence of characteristic mutations provides a rational target for therapy. For example, the finding of BRAF<sup>V600E</sup> in a subset of pLGGs led to the hypothesis that some of the pharmaceuticals designed to inhibit this mutation in melanoma might be active against these tumors (28, 29).

Dabrafenib has improved brain penetration and has demonstrated activity against melanoma brain metastases (30, 31). A multinational pediatric phase I/II study of dabrafenib in patients with known BRAF<sup>V600E</sup> tumors is currently underway (NCT01677741). Recent studies have shown that current BRAF inhibitors are designed specifically for the BRAF<sup>V600E</sup> mutation and can cause paradoxical activation of other BRAF activating mutations (such as the BRAF-KIAA1549 fusion protein) (32). Adding further complexity, there are several different BRAF-KIAA1549 fusions, and several BRAF translocations identified that do not involve KIAA1549 (33).

The advent of improved MAP kinase pathway inhibitors (MEK inhibitors) has led to successful pre-clinical testing in murine models of PA and initiation of a trial of one such inhibitor, selumetinib, in patients with LGG (NCT01089101) (34). Downstream inhibition of the RAS/BRAF/MEK pathway is attractive because it is possible that this class of drug could be used regardless of the upstream mutation leading to pathway activation. However, RAS and BRAF are capable of signaling through other downstream effectors (such as the mTOR pathway), and MEK inhibitors may not target these other pathways effectively (35-37). In preclinical testing, one PA xenograft harboring the BRAF<sup>V600E</sup> mutation responded to MEK inhibition, while another that did not have the mutation was resistant (34).

mTOR pathway inhibition:

Several recent studies have shown that the most aggressive and refractory pLGGs have increased activation of the mTOR pathway (38, 39). The success of the rapalog everolimus in treating SEGAs associated with tuberous sclerosis proved that this drug can shrink mTOR-driven tumors (12, 13),
suggesting it might have activity in other pLGG. A trial of everolimus in refractory/recurrent pLGG has completed enrollment (NCT00782626) and a second phase II trial targeting larger numbers of patients will soon be opening (NCT01734512). A separate study of everolimus in patients with NF1 and LGG is also open to enrollment (NCT01158651). A series of 19 children treated with rapamycin in combination with erlotinib demonstrated prolonged stable disease in 2 children with NF-1 (40). It will be important to determine if increased TORC1 or TORC2 expression correlates with response to mTOR inhibitors, since these rapalogs are likely to primarily inhibit TORC1 (41). New dual TORC1/TORC2 targeting agents such as TORC kinase inhibitors may also be promising drugs for treatment of aggressive LGG.

**MYB and MYBL1 inhibition**

In low-grade fibrillary astrocytomas (WHO Grade II) and a percentage of PAs, genomic rearrangements remove the regulatory domain of c-MYB and the closely related MYBL1 transcription factors (23, 24). These rearrangements leave the transactivating domain constitutively active (23, 24). The over-activation of c-MYB is a known oncogene in leukemia (42). Recently, new inhibitors of c-MYB have been developed, suggesting that these may be eventually be deployed in MYB-rearranged pLGG (43).

**Anti-angiogenic therapy:**

The intense expression of vascular growth factors in PA suggests that these tumors may be dependent on neovascularization for their continued growth (44). Targeting these abnormal blood vessels with the VEGF inhibitor bevacizumab in conjunction with irinotecan led to radiologic and clinical responses in small numbers of children (45). Bevacizumab monotherapy has also been shown to lead to tumor regression and disease stability in patients with LGG (46).

**Immunomodulatory therapy:**

The presence of characteristic mutations in pLGG that are not present in other cells in the body raises the possibility of targeting these abnormal peptides. One way that the immune system can be
 vectored to pLGG is with the immunomodulatory drug lenalidomide. In addition to its ability to alter the immune milieu, lenalidomide has anti-angiogenic and direct anti-tumor effects (47). A phase I study of lenalidomide in patients with refractory/recurrent pediatric brain tumors found that patients with LGG were most likely to demonstrate cessation of tumor progression (47). A phase II study comparing two dose levels of lenalidomide to determine if there is improved response with higher doses (NCT01553149) is ongoing.

A trial is underway investigating if vaccination with glioma associated antigens along with concurrent administration of the immunostimulant poly-ICLC (polyinosinic-polycytidylic acid stabilized by lysine and carboxymethylcellulose) can activate the immune system to attack refractory/recurrent LGG (NCT01130077). Poly ICLC is an immunomodulatory agent that promotes infiltration of T-cells into tumors (48, 49). A phase II study of poly ICLC alone in LGG is currently underway as well (NCT01188096).

Rational For Combination Therapy in Pediatric Low-Grade Gliomas:

Combination chemotherapy has been adapted to pLGGs not amenable to surgical resection (50). Activity of combination chemotherapy in LGGs remains controversial because a number of single agent therapies (see above) have shown results similar in outcome to combination therapy. However, there have not been controlled randomized trials comparing single versus multi-agent therapy in pLGG. When considering why pLGGs may be effectively treated by single agent therapy, it is important to recall the limited malignant capacity of these tumors. Radiation therapy for most pLGGs could be considered optimal single agent treatment based on its ability to stabilize tumor growth. The predominance of mutations along the single RAS/RAF/MEK pathway in the absence of other concurrent oncogenic lesions may account for the activity of low-dose treatment regimens in pLGGs. Two features differentiate pLGGs from most other tumors, both for adults and pediatric patients. The first is the anecdotal observation by many practitioners that patients that have been previously responsive to a particular LGG therapy can reuse the same treatment again, often with good effect. This contrasts with most treatments, where
once a tumor has seen a set of agents in a treatment and then recurred or progressed, further therapy with those same agents is ineffective. The second feature of pLGGs that differentiate them from most other tumors, including adult LGGs, is the overall excellent long term survival of these patients. Even in the context of repeated recurrences through childhood, the majority of pediatric patients will eventually have cessation of tumor growth without the need for further therapy rather than slow transformation to progressively more malignant gliomas, as is routinely observed in adults. This effect has been especially well identified in LGGs in patients with NF-1 and can occasionally even result in spontaneous tumor regression. A similar slowing of growth and eventual growth arrest appears to occur in sporadic pLGGs as these patients enter adulthood.

While clinical trials with a host of targeted agents for pLGGs have only recently started, it is reasonable to begin to consider how combination therapies for these kinds of agents could be developed (51). For pLGGs where the mutational heterogeneity is limited, targeting multiple pathways might be less important. If pLGGs, which are largely characterized by activation of a single pathway (RAS, RAF, TSC, FGFR1 or MYB/MYBL1), then perhaps two inhibitors that target the same pathway would better ensure that any signal that gets through the first blockage (say a BRAF\(^{V600E}\) inhibitor), could be eliminated with a MEK, ERK or mTOR inhibitor further downstream. In melanoma trials of BRAF\(^{V600E}\) targeted inhibitors, the addition of downstream inhibition of MEK improved the activity over either drug alone (52). Early phase trials in adults with solid tumors are investigating combination therapy with TORC1 inhibitors (everolimus or temsirolimus) and BRAF\(^{V600E}\) inhibitors (NCT01596140). Alternatively, dual PI3K-mTOR inhibitors such as BEZ235 are being combined with the MEK1/2 inhibitor MEK162 (NCT01337765). If such combinations are tolerable, the dual activation of BRAF/MEK/ERK and mTOR pathways in aggressive pLGG provides a strong rationale for moving these, or similar drugs, into clinical trials in children.

**The challenges for the rare subtypes of pediatric low-grade gliomas (e.g. PXA, PMA)**
With the development of improved molecular diagnosis of pLGGs, what was once considered to be a limited number of different tumor types have developed into a continuum of tumors with shared molecular defects. Although it has been suggested that the presence of KIAA-BRAF fusions may correlate with improved EFS (53), another study has not associated BRAF molecular alteration with outcome or identified a mutational signature in all members of a specific tumor subtype (54). Thus, it remains to be determined if classification needs to switch from a purely immunohistochemical one to a system that prioritizes these molecular aspects. Current chemotherapy approaches have been effective in the more common forms of pLGGs such as PAs, fibrillary astrocytoma and astrocytoma NOS. Retrospective studies are now being performed to assess what impact the mutational pattern in these tumors had in relation to response to therapy. Although the rare subtypes of pLGGs are less well studied, their responses appear to approximate those mentioned above in reports where they were included in chemotherapy treatment protocols.

Deciding on how to approach rare subtypes of pLGGs such as ganglioglioma, pleomorphic xanthoastrocytoma, dysembryoplastic neuroepithelial tumor (DNT), angiocentric glioma, pilomyxoid astrocytoma and others has become less of a diagnostic issue. Rather, as we move toward identification of the molecular pathways driving these rare subtypes, we recognize that their genomic changes show patterns of overlap between each other in some, but not all cases. The presence of the BRAF V600E mutation for example is identified in approximately 20% of fibrillary grade 2 astrocytomas but not most PAs (21). It is very common in both ganglioglioma (21) and PXAs (55) and occasionally identified in pilomyxoid astrocytomas. Since all of these tumors are potential targets for BRAF V600E inhibitors, should treatment be based on the WHO classification of the tumor subtype or on the specific molecular defect? As mentioned above, a new clinical trial of a specific BRAF V600E inhibitor is now underway and combines all pLGGs with this mutation together into a single protocol. For many of the rarer subtypes of pLGGs, not all of the molecular defects have been identified. For example, while 60% of ganglioglioma and PXA
have the BRAF V600E mutation, we do not yet know what drives the remaining 40%. Similarly, for pilomxyoid astrocytomas, some have the BRAF V600E mutation, some have the KIAA truncated fusion of BRAF and some have neither. It is likely that to optimize therapy in this group of patients, different therapies for these different molecular subgroups of this single entity may be needed.

SUMMARY

This is an exciting time in the treatment of pLGGS. Our integration of the WHO classification with molecular genotypes offers us the opportunity to tailor therapy and ideally minimize toxicity in this patient population. Whether the application of these therapies will improve on the historic PFS seen with traditional chemotherapy and result in durable complete responses is unknown. Moreover, whether biology-driven targeted therapy should be integrated with, or replace, standard upfront therapies such as carboplatin-based regimens or TPCV remains to be tested. Improvements in pre-clinical models of pLGGS, and clinical trials with targeted therapy that will provide some of this information, are already underway.

REFERENCES:

Figure 1. Overview of the major known mutations in pLGG, other promising targets and potential therapeutics. Dark lightning strikes indicate genes known to be altered in LGG, including FGF, NF1, RAS, BRAF, and c-MYB/MYBL1. Many of the alterations in pLGG affect the mitogen activated protein kinase (MAP kinase) pathway, leading to constitutive activation of MEK and ERK. Other alterations less frequently found in LGG are RASSF1 and CRAF. Dabrafenib and vemurafenib are specific inhibitors of only the BRAF^{V600E} alteration. These inhibitors should not be used in non-BRAF^{V600E} containing tumors because they can cause paradoxical activation of other forms of BRAF. MAP kinase pathway blocking alternatives include the MEK inhibitor selumetinib. The transcription factors c-MYB and MYBL1, which are rearranged in a subset of pLGG, can be targeted with the newly identified compound mexicanin-I, a sesquiterpene lactone isolated from the flowering plant *Helenium mexicanum*. Everolimus is a TORC1 inhibitor that has shown activity in subependymal giant cell astrocytoma and is currently being investigated in pLGG. Many pLGG avidly enhance on MRI after gadolinium contrast and show evidence of high VEGF (vascular endothelial growth factor) expression. Immunotherapy appears to be particularly promising for pLGG.
