HLA and Killer Immunoglobulin-like Receptor Genes as Outcome Predictors of Hepatitis C Virus–Related Hepatocellular Carcinoma

Elisabetta Cariani¹, Massimo Pilli², Alessandro Zerbini⁴, Cristina Rota¹, Andrea Olivani², Paola Zanelli³, Adele Zanetti³, Tommaso Trenti¹, Carlo Ferrari², and Gabriele Missale²

Abstract

Purpose: We evaluated the impact of the killer immunoglobulin-like receptors (KIR) of natural killer (NK) cells and of their HLA ligands over the clinical outcome of hepatitis C virus (HCV)–related hepatocellular carcinoma after curative treatment by either surgical resection or radiofrequency thermal ablation (RTA).

Experimental Design: Sixty-one consecutive patients with HCV-related hepatocellular carcinoma underwent KIR genotyping and HLA typing. A phenotypic/functional characterization of NK cells was carried out in patients with different KIR/KIR-ligand genotype.

Results: Activating KIR2DS5 was associated with significantly longer time to recurrence (TTR) and overall survival (OS; \( P < 0.03 \) each). Homozygous HLA-C1 (\( P < 0.02 \)) and HLA-Bw4I80 (\( P < 0.05 \)) were expressed by patients with significantly better OS, whereas HLA-C2 (\( P < 0.02 \)) and HLA-Bw4T80 (\( P < 0.01 \)) were associated with a worse OS. Multivariate analysis identified as parameters independently related to TTR the type of treatment (surgical resection vs. RTA; \( P < 0.03 \)) and HLA-C1 (\( P < 0.03 \)), whereas only KIR2DS5 was an independent predictor of longer OS (\( P < 0.05 \)). Compound KIR2DL2-C1 and KIR3DS1-Bw4T80 genotypes were associated with better TTR (\( P < 0.03 \)) and worse OS (\( P = 0.02 \)), respectively. A prevalent cytotoxic (CD56dim) NK phenotype was detected in patients with both longer TTR and OS. Cytotoxic capacity measured by upregulation of CD107a was significantly higher in subjects with HLA-C1 alone or combined with KIR2DL2/KIR2DL3.

Conclusions: These results support a central role of NK cells in the immune response against hepatocellular carcinoma, providing a strong rationale for therapeutic strategies enhancing NK response and for individualized posttreatment monitoring schemes.
Translational Relevance

Natural killer (NK) cells play a major role in antitumor immune response. The genotypes of NK killer immunoglobulin-like receptors (KIR) and of their HLA ligands are related to the development of hepatocellular carcinoma in patients with hepatitis C virus (HCV) infection. A better understanding of the role played by the immunogenotypic background over hepatocellular carcinoma outcome might represent a major breakthrough to improve the clinical management of patients with hepatocellular carcinoma. Our work shows that the immunogenetic profile is associated with NK-cell function and represents a powerful outcome predictor in HCV-linked hepatocellular carcinoma. These results support a central role of NK cells in the immunoresponse against hepatocellular carcinoma with important implications in terms of development of immunotherapeutic approaches and individualized monitoring schemes after treatment of early hepatocellular carcinoma.

outcome of HCV-related hepatocellular carcinoma after curative treatment by either surgical resection or radiofrequency thermal ablation (RTA).

Materials and Methods

Patients

We evaluated 61 consecutive Caucasian patients with hepatocellular carcinoma with HCV-related liver disease that underwent curative treatment by either surgical resection or RTA at the University Hospital of Parma (Parma, Italy). Hepatocellular carcinoma diagnosis was made by ultrasonography and computed tomography or MRI in selected cases. The type of treatment was decided on the basis of liver function (Child–Pugh score), comorbidities, age, and location of hepatocellular carcinoma nodules. Patients with early hepatocellular carcinoma were evaluated by a multidisciplinary group (interventional radiologist, hepatologist, and surgeon) to decide treatment allocation based on liver function, portal hypertension, number, site, and size of hepatocellular carcinoma lesions. Patients with one or two lesions less than 15 mm in diameter were treated with percutaneous alcohol injection. All patients had not been previously treated for hepatocellular carcinoma.

All patients undergoing liver resection were within Child-A score. Hepatitis B surface antigen (HBsAg) and anti-human immunodeficiency virus were negative for all cases. All patients had the same postoperative follow-up based on bidimensional and contrast-enhanced ultrasonography every 4 months and dynamic computed tomography or contrast-enhanced MRI in any case of appearance of new liver nodules more than 1 cm in diameter or arterial enhancement at the site of previous ablation. The clinicopathologic features of the patients are shown in Table 1.

The study was approved by the local ethical committee (Comitato Etico Indipendente of the Azienda Ospedaliero-Universitaria of Parma, Parma, Italy). Patients gave written informed consent to participate in the study.

KIR genotyping and HLA typing

DNA was extracted from frozen peripheral blood mononuclear cells (PBMC) derived from all patients using the QIAamp DNA Blood Mini Kit (Qiagen). KIR genotypes were determined by duplex real-time PCR (18) on 5 ng DNA in 10 μL containing 1× SsoFas EvaGreen Supermix (Bio-Rad Laboratories), 0.3 μmol/L of each KIR-specific primer, 0.1 μmol/L of each internal control primer, in a Rotor Gene Q thermal cycler (Qiagen) as follows: 2’ 98°C, 5’ 98°C, and 10’ 62°C for 45 cycles. The PCR products were then discriminated by melting (2’ 98°C, 10’ 75°C, and ramping by 0.5°C/s up to 98°C). The KIR genes analyzed are shown in Supplementary Fig. S1.

HLA typing was conducted in all patients by PCR sequence-specific priming on genomic DNA. In all cases showing ambiguities for definition of the HLA-B or C supertypes C1, C2, Bw4, Bw6, and Bw4180/T80 variants,
high-resolution typing was conducted by PCR Sequence Specific Oligonucleotide Probes (Proimmune Co.).

**Immunostaining of NK cells**

In 38 of 61 patients, an aliquot of frozen PBMCs obtained on the same day or the day before treatment was available for phenotypic analysis. PBMCs were resuspended in RPMI-1640 and 8% human serum. PBMCs (3 \times 10^5) were stained with CD3-PerCP (BD Biosciences-Pharmingen) and CD56-APC (Miltenyi Biotec). Cells were analyzed on FACSCanto II flow cytometer (BD Biosciences) by the FACSDiva Software. Frequency of CD56dim and CD56 bright NK cells was defined for each patient evaluating different fluorescence intensity of CD3-CD56+ cells.

**Evaluation of cytotoxic function and IFN-γ production in NK cells**

In 31 of 61 patients, an aliquot of frozen PBMCs obtained on the same day or the day before treatment was available for functional analysis. For the evaluation of the cytotoxic function, PBMCs (1 \times 10^6) were incubated for 14 hours at 37°C in the presence or absence of 1 ng/mL rhIL-15 (R&D Systems). PE/Cy5.5-conjugated CD107a (BD Biosciences) was then added with or without K562-target cells at an effector:target ratio of 5:1. After 1 hour, 10 μg/mL of brefeldin A (Sigma-Aldrich) was added and cells were incubated further 3 hours at 37°C, then harvested and stained for NK-cell surface markers. Percentage of degranulating NK cells was calculated by subtracting CD107a staining after incubation without K562 to CD107a staining after incubation with K562 targets.

PBMCs (1 \times 10^5) were incubated for 14 hours at 37°C with or without 10 ng/mL rhIL-12 and rhIL-18 (Sigma-Aldrich). Brefeldin A (Sigma-Aldrich; 10 μg/mL) was added for the last 3 hours of incubation. After staining with CD56-APC (Miltenyi Biotec) and CD3-APC/Cy7 (BioLegend), cells were fixed and permeabilized using Fix and Perm medium A and B (Caltag Laboratories) according to the supplier’s instructions. Cells were stained with anti-IFN-γ PerCP/Cy5.5 mAb (BioLegend). The proportion of IFN-γ-producing cells was determined by subtracting the percentage of IFN-γ+ cells in unstimulated samples from the one of interleukin (IL)-12/IL-18-stimulated samples.

**Statistical analysis**

The differences between groups of continuous variables were analyzed by Student t test for unpaired data. Categorical variables were compared by the χ² test or Fisher exact test, as appropriate. Survival curves were estimated by the Kaplan–Meier method and compared by log-rank test. For continuous variables, receiver operating characteristic (ROC) curve analysis was used to define threshold levels discriminating subgroups of patients with survival/time to recurrence higher or lower than median values, for subsequent analysis by the log-rank test. Cox proportional hazards regression model was conducted for multivariate survival analysis. Only variables available for all patients and presenting P < 0.1 in the univariate analysis (Table 2) were included in the multivariate model. P < 0.05 (two-tailed) was considered significant.

**Results**

**Clinical outcome**

The study was carried out on 61 consecutive Caucasian patients with diagnosis of HCV-related hepatocellular carcinoma allocated to treatment by either surgical resection or RTA (Table 1). The median overall survival (OS) was 43 months and the median time to the first hepatocellular carcinoma recurrence (TTR) was 17 months. By dividing patients according to the treatment received, it was found that age was significantly higher and liver function worse in RTA-treated patients, whereas hepatocellular carcinoma nodules were on average larger in patients treated by surgical resection. Subjects that carried out surgical resection showed a significantly better OS and TTR compared with patients treated by RTA (Tables 1 and 2). Female sex was associated with significantly shorter OS and Child score with worse TTR; age, number, and size of hepatocellular carcinoma nodules did not affect survival (Table 2). From these results, survival differences related to treatment seem to be most likely due to the treatment allocation criteria, as RTA-treated patients were significantly older and had a worse Child score. Moreover, 3 patients who underwent surgical resection during the same period, died within 2 months from surgery. These patients were not included in the study because the effect of HLA and KIR associations could not be evaluated.

Individual KIRs and HLA expression and their association with disease progression and OS

KIRs frequencies identified in our patients cohort were comparable with the ones previously reported in Caucasian patients from Northern Italy (19, 20), without any significant difference in the prevalence of each reported KIR (Supplementary Fig. S1). The 15 patients carrying the KIR2DS5 gene, that is present in a fraction of the KIR B haplotypes, showed significantly longer TTR and OS (Fig. 1). KIR2DS5 is an activating receptor in linkage disequilibrium with KIR2DS1, that also showed a trend toward a protective effect against recurrence (Table 2). No other analyzed KIRs were significantly correlated to clinical outcome. Homozygous HLA-C1 and HLA-Bw4, I80 variant, were associated with significantly better survival, whereas HLA-C2 and HLA-Bw4T80 were associated with a worse OS (Fig. 1 and Table 2). Multivariate analysis identified as independent parameters associated with outcome the type of treatment (surgical resection vs. RTA) and HLA-C1 for TTR, and only KIR2DS5 for OS (Table 3). By analyzing the effect of HLA-C1 copy number on survival, we detected that HLA-C1 homozygous patients showed significantly longer OS compared with HLA-C1 heterozygous patients, and both longer OS and TTR compared with those with specific HLA, KIR, and HLA–KIR genotypes showing a significant effect on survival analysis. The distribution of HLA molecule is not known. Because almost all our patients were positive for both KIR2DL1 and KIR3DL1 (Supplementary Fig. S1), the effect of compound KIR–HLA genotype on disease progression was not evaluated for these molecules. Altogether, combined survival analysis was conducted for KIR2DL2/2DL3-C1, KIR2DS1-C2, KIR2DS2-C1, and KIR3DS1-Bw4 (I80 and T80). Significant associations were found for KIR2DL2-C1, KIR2DS1/C1+ vs. C1−, KIR3DS1/C1− vs. I80−, and KIR3DS1/C1− vs. I80− (Table 2).

Effect of the compound KIR–HLA genotype on disease progression and OS

The inhibitory receptors KIR2DL2 and KIR2DL3 share the same ligand HLA-C1. Activating KIR2DS2 is in strong linkage disequilibrium and highly homologous to KIR2DL2, however experimental evidence of that KIR2DS2 binds to HLA-C1 is not available at present. KIR2DL1 and KIR2DS1 bind to HLA-C2, whereas KIR3DL1 binds to HLA-Bw4, with higher and lower affinity for I80 and T80 variants, respectively (21). Because KIR3DS1 and KIR3DL1 segregate as alleles of the same locus and show 97% similarity in their extracellular domains, they may share the same HLA ligand. For the remaining KIRs genotyped in this study, the binding HLA molecule is not known.

KIR receptors and their HLA ligands have been implicated as risk factors for several human tumors, chronic inflammatory diseases, and viral infections (22). A recent genome-wide association study (23) identified an association between risk of hepatocellular carcinoma development in patients with chronic hepatitis and a single-nucleotide polymorphism in the gene encoding for MHC-associated chain A (MICA), the ligand of NKG2D, an activating NK receptor (24). This observation strongly supports a relevant role for NK cells in hepatocellular carcinoma pathogenesis.

In the present study, we evaluated the impact of the immunogenetic profile on the clinical outcome of patients with hepatocellular carcinoma undergoing curative treatment by either surgical resection or RTA. Although both these treatment strategies are able to eradicate neoplastic nodule(s), the relapse rate is high since, in addition to the intrahepatic dissemination of primary tumor, de novo hepatocellular carcinoma may develop in the pretumorous environment of liver cirrhosis. The direct clinical consequences of the underlying liver disease have also a major impact on OS after treatment. Because the biologic characteristics of the tumor and the host immune response are both involved in hepatocellular carcinoma progression (25–27), it is likely that the immunogenetic background determining the NK-cell response may play a role on the risk of relapse and ultimately on the survival of patients with hepatocellular carcinoma.

**Discussion**

KIR receptors and their HLA ligands have been implicated as risk factors for several human tumors, chronic inflammatory diseases, and viral infections (22). A recent genome-wide association study (23) identified an association between risk of hepatocellular carcinoma development in patients with chronic hepatitis and a single-nucleotide polymorphism in the gene encoding for MHC-associated chain A (MICA), the ligand of NKG2D, an activating NK receptor (24). This observation strongly supports a relevant role for NK cells in hepatocellular carcinoma pathogenesis.

In the present study, we evaluated the impact of the immunogenetic profile on the clinical outcome of patients with hepatocellular carcinoma undergoing curative treatment by either surgical resection or RTA. Although both these treatment strategies are able to eradicate neoplastic nodule(s), the relapse rate is high since, in addition to the intrahepatic dissemination of primary tumor, de novo hepatocellular carcinoma may develop in the pretumorous environment of liver cirrhosis. The direct clinical consequences of the underlying liver disease have also a major impact on OS after treatment. Because the biologic characteristics of the tumor and the host immune response are both involved in hepatocellular carcinoma progression (25–27), it is likely that the immunogenetic background determining the NK-cell response may play a role on the risk of relapse and ultimately on the survival of patients with hepatocellular carcinoma.
A significant association was observed between KIR2DS5, an activating receptor part of haplotype B, and longer OS and TTR, but the implications of our results could not be further investigated as the ligand of KIR2DS5 has not been identified yet. Whether KIR2DS5 is a marker for a haplotype involved in hepatocellular carcinoma outcome, or whether NK cells bearing KIR2DS5 play a direct role in the clinical outcome due to specific functional characteristics remains to be determined. A survival advantage of patients homozygous for HLA-C1 (HLA-C1C1) and therefore lacking HLA-C2 was also shown, together with an association of HLA-Bw4 variants I80 and T80 with longer or shorter OS, respectively. Homozygous HLA-C1, as well as HLA-Bw4I80, has already been reported as protective against development of HCV-related hepatocellular carcinoma (17). Our results further support the role of these genotypes in human hepatocellular carcinoma, showing their association with survival after curative treatment.

Multivariate survival analysis identified as independent parameters associated with outcome the type of treatment and HLA-C1 for TTR, and only KIR2DS5 for OS. These observations suggest that the therapeutic approach is a major determinant for disease recurrence, together with the HLA-C genotype, but does not represent an independent risk factor for OS, where the immunogenetic profile seems to be the only independent predictive variable.

Previous studies mainly analyzed the implications of the coexpression of inhibitory KIRs and their HLA ligands, that leads to the maturation of fully competent (“licensed”) NK cells both in mice and in humans (28, 29). The opposite situation may occur when activating KIRs are coexpressed with their ligands, as it was shown for KIR2DS1 that recognizes HLA-C2 (30). Indeed the compound KIR2DS1/HLA-C2 immunogenetic profile would lead to the reduced functional competence of NK cells. In patients with hepatocellular carcinoma, we observed that the concurrent presence of KIR2DL2 and HLA-C1 was associated with longer TTR, possibly due to the protective effect of NK cells that had reached full functional competence upon maturation. Consistent with this view, HLA-Bw4I80 (a high-affinity ligand of inhibitory KIR3DL1, expressed by 60/61 patients) was associated with longer survival, whereas the opposite was observed in patients with HLA-Bw4T80, a low-affinity ligand of KIR3DL1 (21, 31). In addition, the combined presence of KIR3DS1 and HLA-Bw4T80 was associated with reduced OS. Previous reports suggested a protective effect of HLA-Bw4I80 in association with activating KIR3DS1 toward the development of HCV-linked hepatocellular carcinoma (17), the progression of acquired immunodeficiency syndrome (32) and, with weak effect, the development of chronic HCV infection (9). Although the binding of KIR3DS1 to HLA-Bw4 has not been convincingly shown so far, these results suggest that a less...
effective interaction of KIR3DS1 and HLA-Bw4T80 in patients with hepatocellular carcinoma might result in reduced NK function and impaired survival. The significance of the association between KIR2DS2/HLA-C1 compound genotype and longer TTR is uncertain: to date, no experimental evidence of HLA-C1 binding by KIR2DS2 is available. Therefore, it cannot be ruled out that this association only derives from the strict linkage disequilibrium between KIR2DL2 and KIR2DS2.

Activating KIR–HLA genotypes seem to increase the risk of developing some virus-related tumors such as cervical cancer due to papilloma virus infection and nasopharyngeal carcinoma associated with Epstein–Barr virus infection (33, 34). An increased risk of developing hepatocellular carcinoma was also reported in patients with chronic HBV infection carrying HLA-C1C1, HLA-Bw4180, and 22 bp-deleted form of KIR2DS4 (KIR2DS4/1D; ref. 35), thus suggesting that increased NK-cell function might represent a risk factor for HBV-related hepatocellular carcinoma. The apparent discrepancy between these observations and those reported in HCV-linked hepatocellular carcinoma (17) might derive from differences in the specific immunopathogenic mechanisms. Because NK cells exert both antiviral and antitumor functions, an enhanced effector phenotype might be protective against tumor development altogether increasing the proinflammatory antiviral environment and the consequent tissue damage, both favoring a preneoplastic condition. However, in our study, the tumor had already developed and immunosurveillance by NK cells would represent an immunologic mechanism affecting clinical outcome.

The impact of the immunogenetic background was further analyzed by phenotypic and functional characterization of NK cells. Higher percentage of CD56dim NK cells, indicative of prevalent effector cytotoxic phenotype, was analyzed by phenotypic and functional characterization of NK cells. Higher percentage of CD56dim NK cells, indicative of prevalent effector cytotoxic phenotype, was associated with both longer TTR and OS, and NK cells from patients carrying HLA-C1 had significantly higher cytotoxic activity. In addition, the combined presence of KIR2DL2/ KIR2DL3 and HLA-C1 was associated with increased cytotoxic function, further supporting the relevance of NK-cell licensing for the achievement of full functional competence. The same association was reported in patients with spontaneously resolving acute HCV infection (13).

This is to our knowledge the first study addressing the relevance of KIR genotype on the prognosis of HCV-related hepatocellular carcinoma after curative treatment. Results suggest a central role of NK cells in the immunoresponse against hepatocellular carcinoma, thus supporting the rationale for developing immunomodulatory strategies aimed at the enhancement of NK response (36) especially in patients showing a favorable immunogenotypic background. In addition, NK-cell phenotype and function may provide information useful to predict outcome and tailor follow-up strategies after hepatocellular carcinoma treatment. Thus our results, if confirmed on larger series of patients, will be relevant for the implementation of individualized posttreatment monitoring schemes and novel therapeutic strategies in patients with hepatocellular carcinoma.
