Abstract

The availability of agents directly targeting tumorigenic and angiogenic pathways has significantly improved the outcomes of patients with advanced renal cell carcinoma (RCC) in recent years. However, all patients eventually become resistant and a substantial percentage experience immediate disease progression with first-line targeted therapy. In addition, patients have variable clinical benefit and/or tolerance to different agents, including drugs within the same class. Thus, the choice of therapy for an individual patient remains empiric at present. Upon this landscape, several molecular biomarkers have been investigated with the purpose of guiding therapy. This review discusses prognostic biomarkers correlating with the outcome of patients independent of therapy, and predictive biomarkers of treatment response, including circulating biomarkers (such as vascular endothelial growth factor [VEGF] and VEGF-related proteins, cytokine and angiogenic factors, and lactate dehydrogenase), and tissue-based biomarkers (such as single nucleotide polymorphisms). Many potential prognostic and predictive molecular biomarkers have now been identified in RCC, although none has yet entered into clinical practice, and all require prospective validation in appropriately designed randomized studies. In the near-future, however, validated biomarkers may become integral to management strategies in RCC, enabling tailored treatment for individual patients to improve clinical outcomes.

Keywords: advanced renal cell carcinoma (RCC), molecular biomarkers, targeted agents
Introduction

Therapy for advanced renal cell carcinoma (RCC) has been dramatically changed by agents directly targeting tumorigenic and angiogenic pathways. First-line treatments, including sunitinib, pazopanib, temsirolimus, and bevacizumab plus interferon (IFN)-α, and second-line options such as axitinib, sorafenib, and everolimus, are associated with substantial improvements in median progression-free survival (PFS) (1–6, 7). Several biomarkers have been identified or are under investigation to better select patients for specific treatments (8). Prognostic biomarkers predict clinical outcomes independent of therapy and predictive biomarkers can be used to optimize treatment selection (9), either from baseline (static markers) – in terms of the likelihood of response or toxicity – or during therapy, as an ongoing marker of treatment response (dynamic markers). Predictive biomarkers of response (or toxicity) are markers that are associated with clinical benefit (or toxicity), and may be followed during treatment.

This review discusses prognostic and predictive biomarkers of response and toxicity under investigation in patients with advanced RCC, and their potential implications for guiding therapy.

Prognostic and/or Predictive Biomarkers

Molecular biomarkers can be grouped according to their physiological location; circulating biomarkers include vascular endothelial growth factor (VEGF) and VEGF-related proteins, cytokine and angiogenic factors (CAFs), circulating endothelial cells (CECs), and lactate dehydrogenase (LDH). Tissue-based biomarkers include single nucleotide polymorphisms (SNPs) and biomarkers related to the von Hippel–Lindau (VHL) and mammalian target of rapamycin (mTOR) pathways. Tables 1 and 2 summarize circulating and tissue-based predictive biomarkers and observations with respect to clinical outcome in patients with advanced RCC (4, 10–28).

Circulating Biomarkers

**VEGF and VEGF-related proteins.** VEGF proteins regulate vascular and lymphatic function (29). There are five mammalian VEGF ligands and three primary VEGF receptor tyrosine kinases (VEGR-1, -2, and -3) (29). Ligand binding to specific VEGFRs results in receptor dimerization and signal transduction. The most studied ligand, VEGF-A (hereafter referred to as VEGF), encodes an endothelial mitogen that has numerous roles including inducing angiogenesis, vasculogenesis, and endothelial cell growth; increasing vascular permeability; promoting cell migration; and inhibiting apoptosis (29).
VEGF is persistently upregulated in clear-cell RCC due to inherent VHL tumor suppressor gene inactivation and drives tumor angiogenesis, facilitating tumor growth and metastasis (30).

VEGF as a prognostic factor

Data from a randomized, placebo-controlled phase III study of sorafenib in previously treated patients with metastatic RCC (mRCC) suggested that baseline VEGF is an independent prognostic factor for PFS and overall survival (OS) in placebo-treated patients (10). This prognostic value was preserved in multivariate analyses. In addition, a small subset analysis of circulating protein biomarkers from the phase III sunitinib vs. IFN-α study suggested that high baseline VEGF correlated with poor PFS and OS in both treatment arms (11). Hypoxia-inducible factor (HIF)-1α and -2α regulate VEGF expression, and HIF-1α expression has been shown in one series to be an independent prognostic factor for OS in a subset of patients with mRCC, although further investigation is required (31).

VEGF and related proteins as predictive biomarkers

High pre-treatment VEGF was associated with a trend towards longer PFS in patients treated with sorafenib compared with placebo (5.5 months vs. 2.7 months) than in patients with low pre-treatment VEGF (5.5 months vs. 3.3 months; $P$ for interaction between VEGF and treatment arm = 0.096) (10, 32). However, changes in VEGF or in soluble VEGFR-2 concentrations from baseline to week 3 or 12 of sorafenib did not predict PFS, somewhat conflicting with the notion that the effect of sorafenib on VEGF is the main mediator of this observation. With regard to the predictive value of on-treatment changes in VEGF, a separate study (12) found that patients with an objective response to sunitinib had significantly larger fluctuations in VEGF ($P = 0.0005$), soluble VEGFR-2 ($P = 0.0003$), and soluble VEGFR-3 ($P = 0.010$) than those without a response. However, smaller studies of sunitinib failed to demonstrate a correlation between reduction in soluble VEGFR-2 concentration on treatment and PFS (13). In addition, low baseline soluble VEGFR-3 and VEGF-C levels were significantly associated with longer PFS following sunitinib in the phase III sunitinib vs. IFN-α study (11) and in patients achieving an objective response in a phase II study of sunitinib in patients with bevacizumab-refractory mRCC (4).

Of note, sunitinib-induced dose-dependent and reversible increases in circulating plasma VEGF have been observed in non tumor-bearing mice (33) and in healthy humans (34); such non tumor-induced increases in VEGF (and potentially VEGF-related proteins) may mask differences attributable to tumor-induced protein changes in responding vs. non-responding patients. Larger studies are required and the influence of previous treatments and of different VEGF detection methods need to
be carefully considered when assessing VEGF/VEGFR biomarker studies (33, 35, 36). Importantly, some angiogenesis inhibitors may interfere with VEGF detection; for example, bevacizumab, a monoclonal antibody that binds human VEGF, can limit the ability of ELISA-based methods to detect VEGF (35, 36).

**Cytokine and angiogenic factors.** As tumor angiogenesis is regulated by an array of pro- and antiangiogenic factors, blockade of angiogenesis with agents that inhibit the VEGF pathway can also affect their balance. As such, baseline levels of CAFs have been studied. Of note, however, a recent study examined current multiplex assays for cytokine detection, and found that these assays vary in their ability to measure serum and/or plasma concentrations of cytokines, and that reproducibility over an extended time frame or among multiple laboratories may be limited (37). This again highlights the need for standardized methodology and may explain some of the inconsistencies in current data on CAFs.

In a retrospective analysis of a small, randomized, phase II study comparing first-line sorafenib with sorafenib plus IFN-α in advanced RCC (38), evaluation of multiple CAFs identified two distinct patient groups: one with elevated proangiogenic and hypoxia-regulated factors and the other group with elevated levels of interleukins and proinflammatory mediators. PFS benefit with sorafenib correlated with a candidate baseline 6-marker CAF proangiogenic signature (osteopontin [OPN], VEGF, carbonic anhydrase IX [CAIX], collagen IV, VEGFR-2, and tumor necrosis factor-related apoptosis-inducing ligand [TRAIL]) (Hazard ratio [HR] = 2.25); patients negative for the signature had a 5-fold reduction in PFS benefit (HR = 0.20; P = 0.0002).

In patients treated with pazopanib in a phase II study (n = 215), those with higher levels of E-selectin and lower levels of interleukin (IL)-6 and hepatocyte growth factor (HGF) appeared to have a longer median PFS (83.9 weeks) than the overall study population (39.3 weeks; P = 0.0016) (39). A 7-factor signature (IL-6, IL-8, HGF, OPN, TIMP-1, VEGF, and E-selectin) correlated with outcome in a similar analysis in pazopanib-treated patients in the phase III trial (vs. placebo). However, as a high vs. low expression of the signature was associated with differing outcomes in both the placebo (median PFS: 11 vs. 24 weeks, respectively; P = 0.001) and pazopanib arms (25 vs. 48 weeks, respectively; P = 0.001), prognostic vs. predictive CAFs could not be clearly separated (40). In a further analysis from this trial, after adjusting for two clinical variables predictive of short PFS (hemoglobin <lower limit of normal and neutrophils >upper limit of normal [ULN]), only OPN and IL-6 in the placebo arm, and OPN alone in the pazopanib arm, were prognostic (41).
In a separate analysis from the phase III pazopanib trial, high IL-6 levels were predictive of improved PFS with pazopanib compared with placebo ($P = 0.009$) (39). In addition, high concentrations of IL-8, OPN, HGF, and TIMP-1 were significantly associated with shorter PFS on pazopanib. Strong prognostic markers of shorter PFS in placebo recipients were high levels of IL-6 ($P < 0.0001$), IL-8 ($P = 0.002$), and OPN ($P < 0.0001$) (39). These analyses of the phase III pazopanib trial are overlapping, but they point to IL-6 as potentially both adversely prognostic in placebo-treated patients and predictive of pazopanib benefit in RCC.

**Circulating endothelial cells and progenitors.** Increased levels of CECs and circulating endothelial progenitors (CEPs) are normally associated with vascular injury, repair, and neovascularization. Several studies have also demonstrated their contribution to tumor vascularization. Given these findings, their utility as prognostic biomarkers is being examined (42). In one study, CEPs were elevated in RCC, but not in patients with VHL syndrome without RCC (43). The role of CECs and CEPs in prognosis or as markers of treatment efficacy in RCC remains to be established.

**LDH.** Currently, LDH is more widely recognized as a prognostic biomarker, being one of the five specific risk factors by which prognosis is evaluated within the Memorial Sloan Kettering Cancer Center (MSKCC) classification system (44). LDH is regulated by the phosphoinositide 3-kinase (PI3K)/AKT pathway and tumor hypoxia/necrosis (45). In the phase III trial of temsirolimus vs. IFN-α, the group of patients with high LDH at baseline ($>1 \times$ ULN) had an HR for OS of 0.56 ($P = 0.002$), with a median survival time of 6.9 months for patients treated with temsirolimus vs. 4.2 months for patients treated with IFN-α. A beneficial effect of temsirolimus on OS vs. IFN-α was not observed in patients with LDH $\leq 1 \times$ ULN (HR = 0.90; $P = 0.51$; OS 11.7 months for temsirolimus compared with 10.4 months for IFN) (16). These data support a prognostic and potentially predictive role of baseline LDH for mTOR inhibitors in RCC. The biological assumption is that LDH elevation connotes a greater activation of the mTOR pathway in these tumors and thus enhanced clinical effect with mTOR inhibition. However, a decline in LDH on therapy was only associated with improved outcome in the IFN arm, not in the temsirolimus arm, refuting the hypothesis that temsirolimus-induced reductions in baseline high LDH/mTOR-driven tumors are responsible for the observed improved OS. In the phase III trial of sunitinib vs. IFN-α, elevated serum LDH was an independent predictor of poor PFS (HR = 1.575; 95% confidence interval [CI]: 1.166 to 2.129; $P = 0.003$) and OS (HR = 2.009; 95% CI: 1.540 to 2.621; $P < 0.001$) in the sunitinib group (46). An independent association between LDH and clinical outcome was also seen in the IFN-α group, suggesting that this observation was related to the prognostic role of LDH in RCC.

**Tumor Tissue Biomarkers**
Predictive factors

**VEGF and VEGF-related proteins.** Pre-treatment tumor expression of VEGFR-2 (either moderate or strong immunohistochemical staining intensity in >10% of tumor cells) has been independently associated with increased PFS in 40 patients with advanced RCC treated with sunitinib (HR = 2.91; 95% CI: 1.15 to 7.41; \(P = 0.0025\)) (47). A small exploratory study of primary tumors from 23 patients with mRCC also found that pre-treatment gene expression of VEGF isoforms VEGF\(_{121}\) and VEGF\(_{165}\) was associated with response to sunitinib at 3 months (\(P = 0.04\) for both) (48). These data from small, retrospective series are not definitive in providing insight into the role of tissue VEGF expression and clinical outcome in RCC, and further study is required.

**VHL gene status.** Data on somatic VHL mutation events and their impact on prognosis has been variable, due in part to small sample-size studies, variations in factors such as treatment regimen and stage of tumors analyzed, and a lack of understanding of how VHL mutations may impact other pathways, for example HIF regulation (49). The first study to demonstrate an association of VHL changes with a prognostic factor linked VHL alteration (mutation or hypermethylation) to a poor risk factor (pt3 tumor stage) (\(P = 0.009\)) (50). However, many other studies have not found correlations between VHL mutational status and common clinical prognostic factors (51–53). In a study of 123 patients with mRCC treated with VEGFR-targeting agents (49% of whom had VHL mutations), there was no significant association between VHL inactivation and either ORR or PFS. The authors hypothesized which specific VHL mutations would be “loss of function” mutations and, while patients with these mutations had a greater objective response rate (ORR), these data can be considered hypothesis-generating only, as there was no functional testing of VHL mutations (17). Further, no association was found between VHL mutation status and clinical outcomes in patients treated with pazopanib (54). Given the nearly universal presence of VHL mutations in clear-cell RCC, it may be that VHL status is not sufficiently differentiating to be associated with clinical outcome. Several mutations present in RCC have recently been described including polybromo-1 (PBRM1) gene in 40% of RCC cases, BAP-1 in 15%, and SETD2 in 10% of cases (55–58). These genes are also located on chromosome 3p and initial studies largely in localized disease have identified prognostic relevance. BAP-1 and PBRM1 mutations appear to be mutually exclusive, with BAP-1 mutation conferring a worse prognosis than PBRM1 mutation (59). A retrospective analysis of 145 patients with primary clear-cell RCC showed a median OS of 4.6 years vs. 10.6 years for patients with BAP-1 and PBRM1 mutations, respectively (HR = 2.7; 95% CI: 0.99 to 7.6; \(P = 0.044\)); a similar risk ratio was shown using data from a second independent cohort (\(n = 327\)) from The Cancer Genome Atlas.
No predictive data regarding these mutations are currently available. Clearly, however, genes located on the short arm of chromosome 3 are integral to the biology of RCC.

**Carbonic anhydrase IX.** CAIX is implicated in regulating cell proliferation in response to hypoxia and is upregulated in approximately 70% of renal tumors (60). The predictive value of CAIX was assessed in treatment-refractory patients receiving sorafenib or placebo in the phase III TARGET trial (61). Despite suggestive retrospective evidence (60), data from the TARGET study did not find CAIX expression to be of predictive or prognostic value in patients with mRCC treated with sorafenib. Similarly, there was no association between CAIX expression and clinical outcomes in patients treated with temsirolimus (20).

**Marker combinations: VHL and c-myc.** An in-vivo analysis of VHL genotype and HIF-α expression in primary clear-cell RCC tumors defined three subgroups of patients with differential HIF-1α and HIF-2α expression: those who express both HIF-1α and HIF-2α, those who do not express either, and a third group of patients expressing only HIF-2α. pVHL-deficient clear-cell RCC tumors expressing only HIF-2α showed elevated c-myc activity, resulting in enhanced proliferation. Patients whose RCC tumors express HIF-2α alone may therefore be uniquely resistant to current targeted therapies, although this hypothesis has not been tested prospectively (18). Consistent with the in-vivo analysis described above, expression of c-myc correlated with outcome in patients with mRCC (n = 80) treated with sunitinib in a recent observational prospective study. Median PFS was 5.4 months vs. 11.4 months in patients with c-myc positive vs. c-myc negative primary tumors, respectively (HR = 2.54; P = 0.0062) (19).

**Predictive factors of response to mTOR inhibitors**

Temsirolimus and everolimus are derivatives of rapamycin and are primarily allosteric inhibitors of mTORC1 function. In a small, retrospective analysis of a phase II trial of advanced RCC patients treated with temsirolimus, objective response to therapy was associated with elevated phospho-S6 expression (P = 0.02) and possibly pAKT expression (P = 0.07) (20). However because of the small sample size, these correlations should be regarded as hypothesis-generating.

One small study suggested that KRAS mutations have been associated with lack of response to everolimus. In a mutational analysis of cancer patients who had received everolimus in phase I and II studies, the presence of KRAS mutations was associated with a significant reduction in clinical benefit from everolimus; of 12 patients with KRAS mutant tumors, 11 (92%) experienced disease progression as their best response. In comparison, only 16 of 31 (52%) patients with wild-type KRAS tumors experienced disease progression as their best response (P = 0.0171) (62).
Single Nucleotide Polymorphisms

SNPs are the most common type of genetic variation and occur throughout an individual’s DNA. Germline SNPs occur in a proportion of the population, although single nucleotide variation can also be acquired during tumorigenesis. Genome-wide association studies can be used to identify germline polymorphisms that are associated with clinical outcome.

**SNPs as predictors of efficacy.** Several studies have investigated SNPs in specific genes involved in sunitinib pharmacokinetics and pharmacodynamics. A retrospective study in 136 patients with advanced clear-cell RCC treated with sunitinib evaluated the association between genetic polymorphisms and clinical response (22). Patients \( (n = 95) \) with polymorphisms in all of three specific genes relating to the pharmacokinetics of sunitinib (encoding, respectively, CYP3A5, NR1/3, and ABCB1) had significantly improved median PFS (13.1 months vs. 7.5 months; \( P = 0.001 \)) and median OS (19.9 vs. 12.3 months; \( P = 0.009 \)) compared with those who did not. Pharmacokinetic but not pharmacodynamic polymorphisms were found to be independent predictive factors for PFS. As clinical benefit from sunitinib may depend on systemic exposure to the drug, with higher plasma levels associated with prolonged PFS (63), these findings suggest that polymorphisms of CYP3A5, NR1/3, and ABCB1 may increase drug exposure by reducing metabolism and excretion (22). Pharmacokinetic data were not available in this retrospective analysis to specifically correlate SNPs with plasma levels of sunitinib and its active metabolite, and additional studies are needed.

In a prospective exploratory study that analyzed 92 SNPs in 34 genes involved in drug pharmacokinetic and pharmacodynamic pathways \( (n = 25) \), significantly greater PFS and OS were found in patients with a *catechol-O-methyl transferase (COMT)* G472A SNP, resulting in a Met/Val polymorphism (PFS = 15 months, OS = 17.2 months) than in those with a Val/Val polymorphism (PFS = 3.3 months, OS = 4.4 months; \( P = 0.005 \) [PFS] and \( P = 0.003 \) [OS]) (23). COMT is involved in metabolism of catecholamines and other substances but its role in the pharmacokinetics of RCC therapies is unknown.

A prospective observational study evaluated the impact of 16 SNPs from nine genes on outcome in 89 evaluable patients who received first-line sunitinib for advanced clear-cell RCC. Two *VEGFR-3* missense polymorphisms (A1559G and G4050T) were significantly associated with reduced PFS on multivariate analysis (A1559G: HR = 3.57; \( P = 0.0079 \); A1559G: HR = 3.31; \( P = 0.014 \); Fig. 1) (25). The authors speculate that those patients with unfavorable polymorphisms have less VEGFR-3 dependence and are thus less susceptible to the VEGFR-3-inhibiting effects of sunitinib. This hypothesis, however, is not supported by observations from clinical trials that patients with low
sVEGFR-3 have a more favorable outcome to sunitinib therapy (albeit after prior treatment with bevacizumab). In addition, polymorphisms in VEGFR3 and CYP3A5*1 were associated with a trend to reduced PFS and OS in response to sunitinib (25).

Another recent retrospective study in 63 patients with mRCC found an association between poor OS and the presence of the combination of a VEGF SNP C936T, located in the 3’ untranslated region (UTR), and VEGFR2 SNP G889A, located in exon 7, after adjustment for prognostic risk group \( (P = 0.03) \), although no single SNP tested (six VEGF and two VEGFR-2 SNPs) correlated with clinical outcome (28).

The predictive value of selected SNPs in patients with RCC treated with pazopanib has also been explored (24). Twenty-seven functional polymorphisms in 13 genes were prospectively correlated with PFS and ORR in 397 patients treated with pazopanib and 96 patients treated with placebo across three clinical trials. Patients with genotypes associated with increased angiogenesis capability and/or increased pazopanib clearance, including polymorphisms in the IL-8 (2767TT) and HIF1A (1790AG) genes, had inferior PFS. Importantly, there was no association between the IL-8 and HIF1A variants and PFS in placebo-treated recipients, suggesting that these markers are predictive of pazopanib efficacy and are not simply prognostic. Genetic analysis of the COMPARZ phase III trial comparing pazopanib with sunitinib attempted to validate this association of IL-8 polymorphisms and survival. Significant associations were found between IL-8 polymorphisms (rs1126647 and rs4073) and both PFS and OS in sunitinib- but not pazopanib-treated patients; however, the association with OS was also significant for the combined treatment population, and HRs for genetic effects were not significantly different between sunitinib- and pazopanib-treated patients (64).

**SNPs as predictors of toxicity.** A multicenter pharmacogenetic association study was performed in 219 patients (including 159 mRCC patients) treated with sunitinib. Investigation of the association between 31 SNPs in 12 genes and toxicity found that genetic polymorphisms in specific genes encoding metabolizing enzymes (CYP1A1, NR1/3), efflux transporters (ABCG2, ABCB1), and drug targets (FLT3, VEGFR-2) of sunitinib were significantly associated with increased risk of adverse events (AEs), including leucopenia, thrombocytopenia, mucosal inflammation, hand–foot syndrome (HFS), and any toxicity grade >2 (26, 27). Additionally, the VEGFR G634T (a 5’UTR SNP) genotype was found to be independently predictive for the prevalence and duration of hypertension by multivariate analysis \( (P \leq 0.05) \) in patients with mRCC treated with sunitinib (28), a finding also noted in patients with metastatic breast cancer treated with bevacizumab (65). A prospective observational study in sunitinib-treated patients with advanced clear-cell RCC found that a specific
SNP (G6986A) in the CYP3A5 gene was associated with significantly increased time on sunitinib before requiring a dose reduction because of toxicity (25).

In addition, an exploratory analysis of data from two clinical studies of pazopanib in patients with RCC ($n = 115$) identified two markers in the hemochromatosis (HFE) gene that may be associated with reversible ALT elevation in pazopanib-treated patients (66). An analysis of patients with RCC who had received pazopanib in phase II ($n = 116$) or phase III ($n = 130$) clinical studies found that the Gilbert’s uridine-diphosphoglucuronate glucuronosyltransferase IAI (UGT IAI) polymorphism was frequently associated with pazopanib-induced hyperbilirubinemia (67).

In summary, several groups have explored candidate SNPs and association with efficacy and toxicity to various VEGF-targeted therapies. Unfortunately, the specific SNPs examined have been largely non-overlapping and across different agents, and to date the results have not consistently identified specific SNPs associated with clinical outcome or toxicity in large populations. Results of individual studies that test multiple hypotheses should also be considered in the light of whether corrections for multiple testing were performed in an effort to reduce the false positive rate (Table 2).

**Discussion and Implications for Therapy**

Despite many exploratory studies, which have identified potential prognostic and predictive biomarkers in RCC, there are currently several obstacles to their clinical use. Potential biomarkers require prospective validation in randomized and adequately powered studies (68). However, few (if any) of the existing studies on tumor biomarkers fully conform to the reporting recommendations for tumor marker prognostic studies guidelines (REMARK) (69), which state that univariate and multivariate analyses should be conducted, and there remain several challenges for the conduct of future studies. Currently, most studies have been performed in sunitinib- and pazopanib-treated patients; more research on biomarkers with other targeted therapies is needed. Furthermore, studies to date have enrolled predominantly Caucasian patients, which may impact the generalizability of their conclusions given pharmacogenomic ethnic differences (22, 25, 70).

Methodological factors, such as adequate and appropriate controls and optimum sample collection, storage, and processing (71, 72), may impact on biomarker stability and study results. The standardization of techniques will be essential for further validation studies. In addition, there are further challenges specific to mRCC, such as difficulty in routinely obtaining biopsies for biomarker analysis, and tumor heterogeneity (73). Robust and specific assays for clinically useful biomarkers with multiparametric, placebo-controlled validation are the goal of continuing research (71). Furthermore, due to the relatively high prevalence of clear-cell RCC, clinical trials of targeted agents...
have typically excluded those with non-clear cell histology. Addressing biomarkers of response in non-clear cell RCC will be an important additional area for future study.

To date, the strongest biomarker evidence in mRCC is from independent prognostic markers or independent predictors of response in phase III studies, or pooled data from multiple studies. Baseline VEGF has been identified as an independent prognostic marker in two randomized phase III studies (10, 11). Moreover, a three-step approach for screening, confirmation, and validation of prospective CAF biomarkers with data from a phase II and a phase III trial of pazopanib treatment identified an association between VEGF and PFS in patients treated with pazopanib (39). Baseline LDH was an independent predictor of response to temsirolimus (16) in phase III studies, and a prognostic factor in the MSKCC classification system (44). There is a large body of evidence investigating SNPs as potential biomarkers, although the research is still in its infancy and requires further investigation. In addition, data are emerging to suggest that specific CAFs or multi-CAF signatures may have predictive value as biomarkers of response to VEGF inhibitors, although large prospective studies are required to validate these preliminary findings. New biomarkers are also emerging. It has been shown that programmed death-1 (PD-1) receptor and programmed death ligand-1 (PD-L1)-positive renal cancers are associated with poorer prognoses than those that are PD-1/PD-L1 negative (74, 75), and agents inhibiting various elements on the PD-1/PD-L1 pathway are currently in clinical development. Whether tumor expression of PD-L1 is predictive of response to these agents in RCC is currently unknown but will be critical to explore as clinical development proceeds. MicroRNA and circulating tumor cells (CTCs) as biomarkers are other expanding fields that have not yet been well explored with advanced RCC treatments; preliminary studies indicate that circulating miR-1233 may be a potential biomarker for RCC patients (76). Moreover, detection of cytokeratin 8/18-expressing CTCs in peripheral blood correlated with poor OS in a study of 154 patients with RCC (P = 0.048) (77). Further studies are required to fully understand the potential of these markers as predictive and prognostic biomarkers in RCC. Progress in validating individual biomarker candidates is likely to be linked to the development of future immunotherapeutics or molecularly targeted agents.

The combination of molecular or genetic biomarkers into a signature may also be valuable for differentiating patient groups in terms of response or potential for toxic effects. Several ongoing studies are analyzing high-throughput genomics to allow the identification of genes functionally required for axitinib (PREDICT-A) (NCT01693822), everolimus (PREDICT-E), and sunitinib (PREDICT-S) response and biomarkers of therapeutic outcome (78). An assay (PREDICT-TOR) is also in
development to measure panels of biomarkers to predict patient response to drugs that target, or are influenced by, the PI3K/AKT/mTOR signal transduction pathway.

Targeted agents have significantly improved outcomes for patients with RCC, to the extent that advanced RCC may be considered a chronic treatable condition in some cases (79); however, there is a clear need to further incorporate molecular factors in clinical decisions. While specific treatment guidelines will be required, the development of validated clinical and molecular biomarkers should facilitate patient management and further improve clinical outcomes by allowing more specific tailoring of treatment to the individual patient.

<td>No</td>
<td>IL-8 may drive an alternative pro-angiogenesis pathway in the presence of</td>
</tr>
<tr>
<td>SNPs associated with toxicity</td>
<td>IL-8 2767 TT vs. AA; ( P = 0.01 ) for IL-8 251 AA vs. TT (( n = 397 )) (24)</td>
<td>VEGF blockade promoting resistance</td>
<td></td>
</tr>
<tr>
<td>-----------------------------</td>
<td>-------------------------------------------------------------------------------------------------</td>
<td>-----------------------------------</td>
<td></td>
</tr>
<tr>
<td><strong>HIF1A</strong> 1790 AG vs. GG</td>
<td>Decreased ORR in patients treated with pazopanib (( P = 0.02 )); decreased PFS in patients treated with pazopanib but not placebo (( P = 0.03 )) (( n = 397 )) (24)</td>
<td>No ( HIF1A ) is a high-activity variant allele possibly associated with increased angiogenesis capability and therefore reduced response to Pazopanib</td>
<td></td>
</tr>
<tr>
<td><strong>NR1I2</strong> CC vs. CT or TT</td>
<td>Increased ORR in patients treated with pazopanib (( P = 0.03 )) (( n = 397 )) (24)</td>
<td>No The ( NR1I2T ) allele may increase pazopanib clearance, reducing systematic exposure via CYP3A4</td>
<td></td>
</tr>
<tr>
<td>Absence of <strong>NR1I3</strong> CAT haplotype; presence of <strong>ABCB1</strong> TCG haplotype</td>
<td>Increased PFS in sunitinib recipients: Absence of ( NR1I3 ) CAT haplotype: 13.3 vs. 8.0 mo; HR = 1.8; ( P = 0.017 ); presence of ( ABCB1 ) TCG haplotype: 15.2 vs. 8.4 mo; HR = 0.5; ( P = 0.033 ) (( n = 136 )) (22)</td>
<td>No ( NR1I3 ) CAT predictive for outcome of sunitinib therapy via regulation of CYP3A4 ( ABCB1 ) TCG haplotype predictive for improved PFS via reduced sunitinib efflux</td>
<td></td>
</tr>
<tr>
<td><strong>CYP1A1</strong> 2455 G vs. A</td>
<td>Increased leucopenia (6.2-fold higher risk; ( P = 0.029 )) and mucosal inflammation (4.0-fold higher risk; ( P = 0.021 )) in sunitinib recipients when the G allele was present in ( CYP1A1 ) 2455A/G (( n = 219 )) (26)</td>
<td>No A relationship between the development of sunitinib toxicity and polymorphisms in specific genes encoding for metabolizing enzymes, efflux transporters and drug targets is suggested in this exploratory study</td>
<td></td>
</tr>
<tr>
<td><strong>CYP1A2</strong> and <strong>CYP2C19</strong></td>
<td>Increased risk of dose reductions due to toxicity in sunitinib recipients: With ( CYP1A2 ), median time to dose reduction: 2.33 vs. NR; ( P &lt; 0.006 ); with ( CYP2C19 ), median time to dose reduction: 2.8 vs. 9.73 mo; ( P &lt; 0.021 ) (( n = 30 )) (23)</td>
<td>Not stated ( CYP1A2 ) and ( CYP2C19 ) SNPs may be associated with toxicity in patients with RCC treated with sunitinib (preliminary analysis)</td>
<td></td>
</tr>
</tbody>
</table>
| **FLT3** 738 CT or CC vs. TT| Decreased leucopenia (2.8-fold reduction in risk; \( P = 0.008 \)) in sunitinib recipients (\( n = 219 \)) (26); less reduction in thrombocyte counts in sunitinib recipients (TT vs. CT/CC): mean thrombocyte count ratios after 4 wks of sunitinib: 0.54 vs. 0.65, \( P = \) | No (26) Not stated (27) The \( FLT3 \) 738C allele may have a protective effect against sunitinib-induced thrombocytopenia. Together with the findings relating to leucopenia, the \( FLT3 \) 738C4T polymorphism appears to have a role in sunitinib-induced bone

Figure Legend

Figure 1. Kaplan–Meier analysis of progression-free survival (PFS) in first-line sunitinib recipients with advanced renal cell carcinoma according to (A) VEGFR3 A1559G AA vs. AG polymorphism and (B) VEGFR3 G4050T GG vs. GT polymorphism. Clinical factors associated with PFS or OS and Memorial Sloan Kettering Cancer Center prognostic classification were included as covariates in the multivariate analysis. P-values were adjusted for multiplicity using Bonferroni’s method.

Figure 1:

A

- A1559G AA
- A1559G AG

HR 3.57 (95% CI, 1.75–7.30)
Multivariate $p_{adjusted} = 0.0079$

Number at risk
A1559G AA 74 32 15 2 1 0
A1559G AG 15 4 0 0 0 0

B

- G4050T GG
- G4050T GT

HR 3.31 (95% CI, 1.64–6.68)
Multivariate $p_{adjusted} = 0.014$

Number at risk
G4050T GG 74 31 15 2 1 0
G4050T GT 15 5 0 0 0 0
