Statement of Translational Relevance

The pace of advances in targeted and immune therapies in Multiple Myeloma (MM) is unprecedented. To keep this momentum going, a framework is proposed outlining key elements and regulatory considerations that will delineate how Minimal Residual Disease (MRD) data could be collected to help standardize correlative analyses across clinical studies. The framework is intended for use by sponsors to incorporate into ongoing or planned trials, without compromising or interrupting their primary trial objectives. Also covered are technologies already impacting MRD assessment in myeloma and emerging approaches that sponsors should consider including in their trials. The current value of MRD to inform clinical care is presented using real world cases of patients with smoldering MM, newly diagnosed transplant eligible and ineligible, and relapse refractory disease, with each case summarizing what is known and questions to be addressed in clinical studies.

Abstract

The development of novel agents has transformed the treatment paradigm for multiple myeloma (MM), with minimal residual disease (MRD) negativity now achievable across the entire disease spectrum. Bone marrow-based technologies to assess MRD, including approaches using next-generation flow and next-generation sequencing, have provided real-time clinical tools for the sensitive detection and monitoring of MRD in MM patients. Complementary liquid biopsy-based assays are now quickly progressing with some, such as mass spectrometry methods, being very close to clinical use, while others utilizing nucleic acid-based technologies are still developing and will prove important to further our understanding of the biology of MRD. On the regulatory front, multiple retrospective individual patient and clinical trial level meta-analyses have already shown and will continue to assess the potential of MRD as a surrogate for patient outcome. Given all this progress, it is not surprising that a number of clinicians are now considering using MRD to inform real world clinical care of patients across the spectrum from smoldering myeloma to relapsed refractory MM, with each disease setting presenting key challenges and questions that will need to be addressed through clinical trials. The pace of advances in targeted and immune therapies in MM is unprecedented, and novel MRD-driven biomarker strategies are essential to accelerate innovative clinical trials leading to regulatory approval of novel treatments and continued improvement in patient outcomes.
1. Introduction

The treatment paradigms in multiple myeloma (MM) have changed significantly over the past 5 years, both for initial management of newly diagnosed disease and during relapse after initial response to therapy. Increasing treatment options with novel drugs and drug combinations have led to deeper responses in MM, associated with improved outcome for patients with newly diagnosed disease and relapsed MM. This in turn has highlighted the inadequacy of traditional response assessment in myeloma that relied entirely on quantitation of the monoclonal protein in the serum and urine using gel electrophoresis and detection of residual protein using immunofixation techniques, along with morphological evaluation of the marrow to define complete response. Complete response (CR) by this conventional definition provided a false sense of disease control, since nearly all patients eventually relapsed despite achieving CR. Subsequent attempts to improve response assessment using serum free light chain (FLC) assay and clonality assessment in the marrow led to designation of stringent CR (sCR), which provided only a modest degree of improvement in assessing the depth of response.

It was in this context that the International Myeloma Working Group (IMWG) updated the MM uniform response criteria incorporating minimal residual disease (MRD) assessment as an additional level of response. The IMWG relied on available data demonstrating a prognostic value for MRD negativity in patients with newly diagnosed or relapsed MM (1). It utilized a minimum cutoff of $10^{-5}$ cells for defining MRD negativity, based on data available at the time of the revision and the availability of technology that could reliably demonstrate residual disease only up to this level of detection. The response criteria were agnostic to the methodology utilized, as long as the method was validated for the level of sensitivity required, and specifically identified flow cytometry or a VDJ gene sequencing approach as acceptable methods. For the first time, the revised criteria also incorporated sensitive imaging techniques into the definition of MRD negativity, based on data from several randomized European trials as well as retrospective data from multiple centers. FDG-PET was the method of choice for incorporation into response criteria, given the available data and the delay in changes seen using conventional MRI compared to functional imaging using FDG-PET. Importantly, technology has continued to improve, and novel flow cytometry and next generation sequencing methods are able to attain sensitivity levels of $10^{-6}$ cells or lower in high-quality bone marrow samples. In addition, mass spectrometry has continued to evolve for detection of smaller amounts of monoclonal protein than immunofixation techniques. Other methods to detect single circulating tumor cells or cell free DNA in the peripheral blood are also being evaluated.
In January 2016, a collaboration of advocacy organizations, patients, research foundations, academia, government (NIH and FDA), and industry was convened by the Foundation for the National Institutes of Health (FNIH) Biomarkers Consortium to update current status of MRD in improving patient care and enhancing the development of new therapies in MM. The resulting white paper (2) summarized state of the science and technology as well as clinical data supporting the use of MRD in MM; and most importantly, proposed studies needed to define MRD as a surrogate endpoint for regulatory purposes and informing clinical decisions in MM.

Significant progress has been made in the 4 years since these original discussions, both in terms of establishing MRD as a regulatory endpoint for clinical trials leading to drug approval, and in design and initiation of clinical trials that are defining the role of MRD testing in routine clinical practice. Several ongoing efforts are attempting to bring together the existing data from large phase 3 trials for surrogacy analysis, a requisite step to obtain acceptance from the regulatory authorities around the world for MRD to serve as a surrogate marker for longer term outcomes. Notably, a recent meta-analysis, the largest to date, reviewed data from 93 publications covering 8098 patients and reaffirmed the importance and strong prognostic value of MRD negativity in improving long-term survival in a heterogeneous cohort of patients with MM (3). Also, there are efforts being led by the MM community in collaboration with industry partners which are at the stage of MRD data aggregation and analysis for submission to health authorities. We anticipate that these efforts will eventually lead to increased utilization of MRD as an endpoint for clinical trials with regulatory intent.

Even more progress has been made in the design of clinical trials that incorporate MRD testing at various stages of therapy to inform subsequent treatment decisions. In our previous white paper (2), we suggested several potential clinical trial designs to evaluate the value of MRD at various stages of MM. Many of these designs have now been implemented, and almost 50 Phase III trials are currently actively enrolling using MRD-directed treatment assignment or MRD as an endpoint (Table 1). These trials are designed to ask clinically-relevant questions including: defining the ideal duration of maintenance therapy post autologous stem cell transplantation; defining whether MRD-directed treatment intensification is beneficial in patients who do not achieve MRD negativity after induction therapy with triplet combinations or those who remain MRD positive at 1 year of post-transplant maintenance. Given the considerable progress made over the 4 years since our initial white paper, we here review the progress and update recommendations regarding the current role of MRD testing in clinical trials and routine clinical practice, as well as in new drug registration.
2. Scientific and Technological Considerations

A number of large professional society meetings focused on hematological malignancies have included a point/counterpoint debate on whether MRD assessment is "ready for prime time" in clinical management of patients with lymphoid malignancies including MM. While these sessions are useful for introducing the concepts of MRD to practitioners, they belie and obscure the fact that MRD has become a fundamental gauge for clinical management in various cancers. The concept of remission in hematologic malignancies was once based on clinical exam alone, then on the enumeration of morphologically aberrant cells in the bone marrow or blood from a patient, then by conventional flow cytometry, which provided a sensitivity based on practical application (not on biology) of $10^{-4}$ cells, and then by analyses of immunoglobulin light or heavy chains in the blood (or urine). At each point in time when these measures were adopted for clinical care, they represented an increase in sensitivity over what had existed before. Their utility, however, was only relevant once therapeutic interventions existed that could lower the tumor burden to a level at which such increased sensitivity was necessary. Physicians treating patients with leukemia, lymphoma, or MM have evolved their practices as each new more refined, standardized, accurate, and sensitive measure of residual disease has been introduced. Initially, the clinicians’ response was often exasperation exemplified by responses to the sensitivities of current new technologies, “I should be so lucky as to have to worry whether my patient still has one malignant cell within one million normal hematopoietic cells”. Fortunately, for one after another indication, treatment has become more and more efficacious, and therapeutic options for a given patient have markedly increased. Today, it is possible to approach a patient with MM with the prospect of long-term control. Thus, in-depth assessment of residual tumor burden and kinetics of residual tumor growth over time have become essential to patient-physician discussions of a therapeutic plan and decisions of whether to change, discontinue, or intensify a given treatment course. In fact, physicians have started incorporating MRD determination as an aid in their real time clinical management decisions (4). In this section, several advances in the determination of MRD are described. Utilization of these methods in clinical trials, in drug development, and in real world patient management are discussed in subsequent sections.

Strengths and weaknesses of the various MRD technologies have been well described elsewhere and will not be discussed in details here. Regardless of which “next generation” technology (Next Generation Flow or NGF, Next Generation Sequencing or NGS, imaging, mass spectrometry-based
paraprotein analyses, etc.) is employed, some basic principles apply to its incorporation into clinical trials and real time patient management. Single point in time assessment of MRD is a measure of tumor burden, not tumor biology. On the other hand, achievement of such deep remission might reflect a favorable biology. Any threshold of such tumor burden (e.g., $10^{-4}$, $10^{-5}$, $10^{-6}$ cells or undetectable) is useful in order to provide consistency when comparing treatment arms or stratifying patient populations into different arms of therapeutic intervention and ultimately in the future in choosing treatment options in real world practice. Such thresholds provide information at the population level on average therapeutic efficacy. However, MRD is a continuous variable and for individual patient management any MRD value must be considered in the overall context of prior treatment regimens, other diagnostic tests and risk markers, as well as all of the signs, symptoms, co-morbidities, and quality-of-life factors that are relevant to that particular person. Determination of MRD at a single point in time may have prognostic significance, but quantitative, accurate, standardized, and sensitive MRD determinations may provide greater information relevant to tumor biology and likelihood of relapse when performed in a sequential fashion over multiple time points during a continuum of care to establish the trend and pace of the change in tumor burden.

2.1 Next Generation Flow (NGF) cytometry

Multiparametric flow cytometry (MFC) is a widely available, fast and highly applicable technique for detection and enumeration of bone marrow (BM) plasma cells (PCs). In addition, it allows clear cut and highly sensitive discrimination between normal (i.e. polyclonal) and clonal PCs based on their uniquely distinct (normal vs. aberrant) immunophenotypic characteristics, even when tumor PCs are present at very low frequencies, e.g., MRD (5-7). Early studies and more recent investigations have highlighted the value of MRD monitoring by MFC for: i) improved evaluation of response to therapy, particularly among patients that reach a complete response (CR); ii) prognostic stratification of MM patients after therapy; and iii) to modify treatment in the settings of clinical trials for both transplant eligible and transplant ineligible patients (8-22). However, none of the referenced studies have definitively demonstrated yet in a randomized fashion that modifying treatment in an MRD-positive patient converts them to MRD-negative and improves outcomes, something being currently addressed through ongoing clinical trials. In parallel, these studies also showed that conventional MFC MRD approaches are associated with several important limitations when compared with molecular MRD approaches, particularly a lower sensitivity and lack of standardization (23, 24).
Highly sensitive NGF MRD approaches have been developed in the last 5 years by EuroFlow to overcome most limitations of conventional MFC MRD techniques (23, 25, 26). This novel NGF approach for MRD in MM is based on a more efficient sample preparation protocol for acquisition of >10 million BM cells, optimized and well-tuned 8-12 antibody combinations (25), and innovative automatic data analysis strategies and software tools that have resulted in increased sensitivity (vs conventional 4-10-color MFC approaches) of $10^{-6}$ (26). Importantly, NGF can be applied in virtually every MM patient, even in the absence of a diagnostic sample. Furthermore, NGF MRD also provides information about the quality of the BM sample and the potential presence of hemodilution, which is critical for early identification of false negative MRD results (23, 26, 27). Because of these clear advantages and its standardized nature, MRD detection in MM by the EuroFlow NGF approach has been recognized by the IMWG as the reference method to define Flow MRD-negativity after therapy (1). This is of utmost importance, since the clinical impact of high-sensitivity MRD detection by NGF (26) has been recently validated in the settings of both real-world MM patients (28) and the PETHEMA/GEM 2012MENOS65 clinical trial (24). Notably, only 7% of MRD-negative (MRD <2 x 10^{-6} cells) cases in the GEM/PETHEMA trials showed disease progression (mostly related to extraosseous disease) with an 82% and 88% reduction in the risk of progression and death, respectively, and hazard ratios of 0.18 (95% CI, 0.11-0.30; P <.001) and 0.12 (95% CI, 0.05-0.29; P <.001), respectively, overcoming the poor prognostic value of high-risk cytogenetics at diagnosis in cases that achieved MRD-negativity by NGF (24). Although the recently extended use of anti-CD38 antibody-based therapies could interfere with CD38-based NGF detection due to bound antibodies at the surface of MM cells, combined use of alternative (e.g., multiepitope and nanobody) CD38 conjugates and the NGF-based automatic data analysis strategies have allowed for robust detection of MRD, even in patients receiving anti-CD38 therapy (26, 29, 30). Meanwhile, occurrence of extraosseous disease in this subset of patients highlights the complementarity of BM-based MRD assessment with other approaches including MRD detection in blood by NGF (30), Qip-Mass Spectrometry (31) and particularly, imaging techniques (24, 32).

2.2. Next Generation Sequencing (NGS) MRD

DNA- based assessments of immune receptor clonality (e.g., Southern Blot, PCR) have been employed to address clinical research questions for many years (33, 34). It has only been within the past ten years that advances in knowledge to develop a comprehensive “immunosequencing” high throughput
method of enumerating, specifying, and quantifying each and every B- and/or T-cell in a sample of interest have come together to allow for a DNA-sequence based immune receptor repertoire approach to real time clinical questions. One of the first and most obvious applications is the determination of MRD in lymphoid malignancies. The technology behind next generation sequencing (NGS) has been well described elsewhere (35, 36). The assay is robustly quantitative, which has been ensured by primer design and concentration adjustments, so that every possible V-J combination is amplified equivalently. The sensitivity of the assay is simply a function of the amount of genomic DNA that is analyzed. Because of the absolute specificity of most CDR3 regions, only a single event (the presence of a single sequence within the sample) is required to make a call as to the presence of a clone of interest. If one million cells are analyzed, the sensitivity of the reaction approaches $10^{-6}$ cells. At the patient level the assay can detect MRD in >95% of extracted gDNA samples from that patient if, on average, there are ~2 or more malignant-cell equivalents per the number of total cells assessed in the patient sample. As will be discussed in the Regulatory Section below, the NGS-based assay of immune receptor repertoire profiling developed by Adaptive Biotechnologies (clonoSEQ) is currently the only assay cleared by the US FDA for MRD determination in bone marrow from patients with MM.

There are numerous studies that demonstrate the utility of this assay for the determination of response to therapy, prognosis, and monitoring of disease status. For example, in recent study using this assay for the assessment of patients with MM pre or post maintenance demonstrated that the level of MRD correlates with outcome, and that the deeper the level of MRD either pre or post maintenance (down to a level of less than $10^{-6}$ cells), the better the prognosis (37). In this study, more patients in the autologous stem cell transplant (ASCT) treatment arm achieved NGS-based MRD negativity than in the control arm. However, the best prognostic marker was the achievement of NGS-MRD negativity, regardless of the treatment arm to which a patient was assigned. Similar findings have emerged from other clinical trials. For example, in a comparative study of patients stratified to receive either VMP alone or daratumumab (dara)-VMP, more patients in the arm including dara achieved NGS-MRD negativity; however, the outcome for all patients achieving NGS-MRD negativity was the same (38). This again supports the concept that achieving MRD negativity may be more important than how one reached that state.

It should also be mentioned that the same chemistry and algorithmic principles described here for NGS-based MRD analyses can be applied to any situation in which elaborating, specifying, and quantifying the immune response is important. This broadens the application of NGS-based immune research.
receptor repertoire analysis to indications in immunotherapy, infectious disease, autoimmunity, vaccine response, aging, and general considerations of individual or population health status (39-41).

2.3 Toward blood-based MRD approaches

Advancements in technologies to assess MRD, including NGF and NGS, have provided real-time clinical tools for the sensitive detection and monitoring of MRD in MM patients (28, 42). However, the routinely used MRD assays rely on information obtained from repeated BM aspirates, which are invasive and may contribute to false negatives due to the multifocal “patchy” nature of the disease in the BM. Liquid biopsy-based assays could be very useful to implement into MRD assessment as they can: (i) provide accessible repeatable measurements for routine monitoring, (ii) detect total tumor burden reflective of disseminated disease and undetected lesions to stratify patients by recurrence risk, and (iii) provide comprehensive information on heterogeneous genetic alterations that can help guide therapy for earlier intervention (43). While some blood-based approaches, such as mass spectrometry methods, are now very close to prime time, others utilizing nucleic acid-based technologies are still developing and will prove to be important complementary tools to assess the biology of minimal residual disease.

2.3.1 Mass Spectrometry Methods

Mass spectrometry methods to detect the M-protein in blood offer a promising, less-invasive alternative to BM-based MRD testing. These methods can detect the M-protein at lower concentrations than serum immunofixation, better distinguish therapeutic antibodies from M-proteins, and detect post-translational modifications (i.e., glycosylation), which may be relevant for identifying amyloidosis (44, 45). Importantly, mass spectrometry methods have the ability to distinguish between myeloma-derived monoclonal proteins and therapeutic monoclonal antibodies.

Mass spectrometry methods are based on the fact that each immunoglobulin has a unique amino acid sequence and therefore a unique mass. Although a variety of methods have been developed, they all involve the same general steps: enriching immunoglobulins from serum, processing the enriched proteins into smaller components, and measuring the mass of the components. Data are analyzed for the presence of the patient’s M-protein-specific mass, which is used as a marker of disease and is constant over time.
Matrix-assisted laser desorption/ionization mass spectrometry (MALDI-TOF MS) is a rapid, high-throughput technique that has the potential to replace current electrophoretic methods for M-protein detection. The Mayo Clinic currently offers the MASS-FIX assay as a laboratory-developed test. This method is more analytically sensitive and specific than serum protein electrophoresis and immunofixation (46, 47), and provides similar clinical sensitivity for the detection of monoclonal gammopathies (48). Another similar method is being developed by The Binding Site with the goal of producing an FDA-approved, commercially-available assay. Both methods follow the signal from intact light chains to detect M-proteins. However, they differ in technical details, particularly the immunoglobulin purification step, and a head-to-head comparison of these techniques has not yet been reported.

More sensitive liquid chromatography-mass spectrometry (LC-MS) methods have also been developed to detect M-protein but remain in the research realm. A method termed monoclonal immunoglobulin rapid accurate mass measurement (miRAMM) follows intact light chains, and was reported to be about 100 times more sensitive than serum immunofixation (49). Other LC-MS methods track clonotypic peptides as a marker of disease. In these methods, enriched immunoglobulins are digested with an endopeptidase, most commonly trypsin, and patient specific peptides from the immunoglobulin heavy and light chain variable regions are monitored by LC-MS. Reported detection limits of these clonotypic peptide methods range from 0.01 mg/dL to 4 mg/dL (45, 50-52).

Currently, the field is still developing these techniques and evaluating how to best use them. Some studies comparing mass spectrometry results to bone-marrow-based MRD assays have found that the M-protein can be detected when BM-based tests are negative (53-56). And, a recent study found LC-MS to be a better predictor of PFS (56). Prior to the incorporation of these methods into clinical laboratories, work is needed to better understand the clinical utility of low-level M protein measurements. Questions remain regarding the half-life of immunoglobulins and the level of sensitivity needed for detecting the M protein in the setting of MRD.
2.3.2 Circulating cell-free DNA for MRD assessment

Liquid biopsies that track tumor mutations present in circulating cell-free DNA (cfDNA) isolated from blood plasma have become a promising minimally invasive tool to characterize and monitor many cancers (57-60). Multiple groups have executed studies that revealed cfDNA dynamics and high concordance of clonal somatic mutations and copy number alterations between BM and cfDNA of MM patients (61-64). However, extending these findings to implement cfDNA profiling for MRD assessment has remained challenging due to limitations in detection of the low abundance of circulating tumor DNA (ctDNA) from normal cfDNA derived from peripheral blood cells (65). Ultimately, many current methods lack the capacity to detect MRD when the fraction of ctDNA in the bloodstream is lower than twice the inverse of the number of copies of each gene in a given sample, referred to as the genomic equivalent (GE) limit (66).

Ultra-deep targeted sequencing has significantly improved the detection of ctDNA present at low concentrations, although sensitivity is driven by the number of tumor mutations available to track. To date, the validity of cfDNA profiling in the MRD setting in MM has been limited to a small subset of clinical studies (42, 67, 68). Most recently, the first comparative prospective study tracked all clonal immunoglobulin gene rearrangements using NGS in paired cfDNA and BM samples for MRD assessment in 42 MM patients (42). The study demonstrated there was no correlation for MRD between cfDNA and BM, with only 49% consistency between the paired samples. The most frequent discrepancy observed was undetectable MRD in plasma, which was positive in the BM. This suggests different NGS strategies are needed to increase the sensitivity of detection of low-frequency variants without compromising specificity (69, 70). An alternative strategy that remains to be tested in MM is tracking a larger number of patient-specific tumor mutations based on a tumor-derived mutation fingerprint. This strategy has successfully been shown to increase the likelihood that the targeted mutations will be captured when the tumor fractions in the blood are below the GE limit (66).

Alternatively, large, targeted sequencing panels that incorporate frequently mutated genes, frequent copy number alterations, V(D)J rearrangements and translocations, as well as minimize template DNA losses during library preparation and suppress background errors, may also be applicable and have yet to be described (70-72).

To validate the utility of ctDNA in the MRD setting, comparative studies are needed that incorporate both BM and cfDNA and assess MRD with different methodologies. Additional efforts towards the
design of targeted sequencing assays and bioinformatics techniques are likely required before they can be proposed as standard approaches. Sufficiently powered prospective investigations will also be needed to prove that ctDNA detects a window of intervention before current BM-based methods or is complementary in some way, and that clearance of ctDNA levels is reflective of disease control (73).

2.3.3 Single cell RNA-sequencing (scRNA-seq)

Single cell RNA-sequencing (scRNA-seq) offers high-throughput and high-resolution analysis of gene transcription on a cell by cell basis. The single cell approach provides benefit by allowing resolution of malignant plasma cells from stromal and immune cells of the microenvironment compared to bulk sequencing, which yields an aggregate of transcriptional activity from unknown cells from a specimen (74-78). Therefore, this sensitivity facilitates the detection of rare malignant cells that constitute MRD. The power of the technology lies in the combination of single cell resolution with transcriptional activity. Molecular signatures of the evolution and progression of disease have been found in plasma cells, as well as the non-tumor cells of the BM microenvironment (79-82). Therefore, scRNA-seq may be used to select appropriate targeted therapies according to the identification of resistant or sensitive populations of cells, based on specific gene mutations, splice variants, and common rearrangements. For example, t(11;14) and high BCL2 mRNA appear to be predictive markers for response to venetoclax (83), and certain gene expression signatures have been found to predict for response to proteasome inhibition (84).

However, several challenges need to be overcome before scRNA-seq can enter routine clinical practice (85). At the technical level, sample preparation is time consuming and loss of polyadenylated RNA at low levels of gene expression may lead to amplification bias (86). Therefore, there needs to be a standardization and simplification of the workflow both in sample preparation and bioinformatic analysis to ensure accuracy and reproducibility among patients and centers. Furthermore, evidence to support the use of targeted agents in response to specific transcriptional signatures is in its infancy.

Despite these considerations, scRNA-seq has the potential not only to be a highly sensitive technique for MRD determination, but also to provide detailed information to guide subsequent therapeutic intervention. In essence, it can identify the disease at the earliest opportunity and provide a solution in the same test. The use of scRNA-seq to monitor intra-clonal heterogeneity in individual patients has the potential to take the care of patients with myeloma one step closer to true precision medicine.
2.4 Imaging

For the longest time, imaging has been limited to assessment of myeloma bone disease. However, since a multitude of studies have shown that modern cross-sectional whole body imaging techniques like positron emission tomography with computed tomography (PET/CT) and magnetic resonance imaging (MRI) provide a comprehensive overview of the tumor burden beyond osteolytic lesions including extramedullary disease (EMD), these techniques have been investigated as methods to assess residual disease after therapy (87). This is particularly important because other techniques, which rely on bone marrow specimens are by nature limited to sampling a very small area of the body. Besides the patchy infiltration of BM plasma cells (BMPCs) and the presence of EMD (88), recent prospective studies serially monitoring patients with functional imaging and focal lesions (FL) biopsies demonstrated that MM entails spatial heterogeneity, with possible coexistence of different disease clones with different genomic profiles in the BM versus FLs (89). The larger the FL size, the greater the heterogeneity (90). Therefore, whole body imaging provides important complementary information about residual disease after therapy, and also about early relapse. EM sites of clonal proliferating PCs in a context of BM MRD negativity are more frequent in patients with EMD at diagnosis (5-10%) or with para-medullary plasmacytomas (91).

Fluorodeoxyglucose ($^{18}$F-FDG)-PET is an excellent imaging tool to assess tumor metabolic activity and monitor response to treatment, due to its ability to distinguish between active and inactive (e.g., fibrotic) disease. In addition, low dose CT, which is typically done for localization along with FDG-PET, constitutes a precise screen for bone and extra-medullary findings (92).

Several studies have demonstrated an unfavorable prognostic role for PET positive lesions after completion of therapy (93-96). Conversely, in patients achieving complete remission (CR), FDG-PET/CT negativity after ASCT predicted a lower risk of progression or death in patients with conventionally-defined CR than in patients with metabolically active sites of disease (97, 98). Moreover, in patients achieving MRD negativity by flow cytometry with a sensitivity of $10^{-5}$ cells, imaging either by PET/CT or whole body-diffusion weighted imaging magnetic resonance (WB-DWI-MRI) was positive in 12% of the cases and associated with a shorter progression-free survival (PFS) (99). In contrast, patients achieving an MRD-negative CR during salvage therapy frequently had FLs (50%). Also, it has recently been shown that patients obtaining PET FL normalization upon therapy have comparable prognosis to patients without baseline increased metabolism, suggesting the value...
of treating until suppression of glucose metabolism (100). The complementarity between imaging (either FDG-PET/CT or WB-DWI-MRI) and BM techniques in defining the prognosis of patients was demonstrated by two prospective studies, using flow cytometry with a sensitivity of $10^{-4}$ (10) and $10^{-5}$ cells (99).

On the basis of the above-reported results, 18F-FDG PET/CT is currently considered the preferred imaging technique for evaluating and monitoring metabolic response to therapy (87). However, it has been reported that in 10 to 15% of cases, PCs may not be 18F-FDG-avid due to lack of hexokinase enzyme, which is responsible for FDG trapping in the cells (101). In these patients, FDG PET/CT is not an appropriate tool to evaluate metabolic response to therapy. In addition to 18F-FDG, new PET/CT tracers targeting different metabolic pathways or receptors expressed by PCs may represent potentially more sensitive and specific molecular imaging biomarkers, and have been preliminarily investigated in limited series of MM patients or in mouse models (102). PET imaging targeted to CXCR4 (103, 104), CD38 (105, 106), and VLA-4 (NCT03804424) has advanced into translational clinical trials, bringing us closer to powerful imaging options for MM. Radiolabeled antibody imaging may be advantageous, as it is imaging tumor cells with antigenic expression regardless of metabolic processes, resulting in earlier and more specific assessment of response. For example, all MM cells express CD38, making it an excellent focus for targeted imaging and therapy. Daratumumab is an already FDA-approved monoclonal antibody therapy for MM that targets CD38. Conjugating daratumumab with the positron emitting radio-isotopes Copper-64 (64Cu) and Zirconium-89 (89Zr) has allowed for the creation of immunoPET tracers for MM imaging. 89Zr-Daratumumab has demonstrated the ability to detect MM in early clinical trials (107) when it was not detected by FDG-PET/CT and other clinically-standard imaging methods. More advanced clinical trials for these immunoPET agents are planned.

However, the lower availability of these newer tracers, inter-patient tumor heterogeneity regarding specific targets, as well as the lack of prognostic data and standard reporting, prevent any definite conclusion from being drawn at this time. As with BM techniques, standardization of imaging criteria and definition of cut-offs for positivity/negativity, highly important to allow for data reproducibility and harmonization, is currently ongoing. A standardized definition of PET complete metabolic response has been proposed considering the uptake of the liver as threshold, and is currently under confirmation in independent prospective series of patients (108).
Conventional MRI without contrast agents has been used for response assessment in several clinical trials, in addition to serological and BM derived parameters. Two studies using MRI of the spine and pelvis and whole body MRI in a total of 711 patients treated with high dose chemotherapy protocols showed that residual lesions after completion of the most aggressive treatment had a significant adverse prognostic significance (109, 110). A later study again comparing axial MRI (including spine and pelvis) with PET/CT in 134 MM patients treated in a multi-center trial showed that PET/CT was superior to MRI with regards to prognostic significance after therapy. The most likely explanation has been examined in the first study of this kind showing that treatment response in MRI appears delayed, with FLs of MM disappearing more slowly because MRI is not able to differentiate between vital and necrotic tissue within preexisting osteolytic lesions (109). Interestingly, a change of lesions into a more liquid or cystic appearance was associated with a higher rate of complete remissions, but also with a higher proliferation index in gene expression profiling (111). A further development of MRI is DWI, which measures the movement of water molecules in the investigated tissue. This Brownian movement is in part limited by lipophilic cell membranes and promoted by tissue perfusion, which in turn gives DWI the ability to assess cellularity and microcirculation in the bone marrow (112). Recent studies suggest that whole body DWI might be equivalent or even slightly superior to FDG PET/CT in the assessment of MRD (113).

In summary, at this time PET/CT is the most widely available and most reliable imaging technique for the assessment of residual disease in areas outside of the bone marrow, and should be added to assess remission, especially within clinical trials.

3. Regulatory Considerations

3.1 FDA Perspective on Regulatory considerations for MRD Assessment and Incorporation into Clinical Trials

There is an interest in the MM community to evaluate new sensitive markers of response, like MRD, to provide an improved and early estimate of activity of drugs to expedite drug development. While available evidence suggests that MRD as a general measure of tumor burden in patients with MM has multiple potential regulatory and clinical uses as a biomarker, the clinical and regulatory uses are very different. For MRD to function as an effective regulatory tool, several aspects within each context of
use need to be addressed, such as underlying disease, patient heterogeneity, therapeutic context, target of therapy, or a combination of disease parameters.

Regardless of the registrational intent for a trial, it is important that the trial is adequate to meet its stated objectives (21 CFR 312.42 (b)(2)(ii)). If MRD assessment is a key component of the trial objectives, the MRD assessment should provide interpretable data. A review of applications submitted to the Food and Drug Administration (FDA)'s Division of Hematology Products between 2014 and 2016 that included MRD data highlighted several issues with MRD assessments in regulatory submissions. In more than half of the submissions, data were considered inadequate (31%), or were not proposed for inclusion (23%) because of missing or disparate data points, high amounts of test failure rate, incomplete test characteristics, and incomplete planned statistical analysis (114).

The recent FDA guidance “Hematologic Malignancies: Regulatory Considerations for Use of Minimal Residual Disease in Development of Drug and Biological Products for Treatment Guidance for Industry” was published to help sponsors planning to use MRD as a biomarker in clinical trials conducted under an investigational new drug application (IND) or to support marketing approval of drugs and biological products for treating specific hematologic malignancies (115). This guidance addresses several aspects including assay considerations, the strength of evidence and data that are required to support MRD as a surrogate endpoint, and considerations for using MRD as a patient selection factor.

Specifically, with respect to assay selection, FDA is agnostic as to which technology platform is used in clinical trials assessing MRD as long as the assay to be used is analytically validated for its context of use in the trial, i.e., the assay demonstrates acceptable sensitivity, specificity, accuracy, precision, and other relevant performance characteristics as defined under a specified technical protocol. The assay validation considerations may differ based on the specific technology platform, e.g., cellular vs molecular platform. If the assay is not approved or cleared for the intended use and the trial is considered a significant risk device trial, an investigational device exemption (IDE) may be required to use the assay in the clinical trial. For a trial considered a nonsignificant risk device study, the sponsor should submit abbreviated information about the assay, as stated in the MRD guidance (116). It is important to note that FDA cleared or approved assays have been analytically validated for the specific context of use. As described above, the Adaptive clonoSEQ assay is an in vitro
diagnostic that uses multiplex polymerase chain reaction (PCR) and NGS to identify and quantify certain gene sequences in DNA extracted from BM of patients with acute lymphoblastic leukemia or MM, and blood or BM from patients with chronic lymphocytic leukemia (CLL). The clonoSEQ assay’s intended use is to measure MRD to monitor changes in burden of disease during and after treatment. The use of an approved assay outside of its intended use, e.g., use of the approved clonoSEQ assay to monitor MRD in peripheral blood samples of patients with MM, may dictate additional assay and informed consent considerations. It is important for Sponsors to interact with the regulatory agency when considering incorporating MRD assessments into a clinical trial (117).

In MM clinical trials, MRD can be used in a variety of ways that may expedite drug development. MRD can be used for patient selection, stratification or enrichment of the trial population, to guide treatment decisions, or as an endpoint. There are specific considerations and potential risks associated with each use of MRD in the clinical trial setting. With patient selection or enrichment, MRD may be used to identify a patient population that is at high risk of relapse or poor outcome. In this setting, it would be important to identify the MRD threshold which best portends poor outcome and merits further intervention. When using MRD to guide treatment decisions, the threshold for intervention should be adequately supported, but there are additional considerations for these trial designs. Randomized intervention based on MRD status (e.g., randomization of MRD positive patients to additional therapy vs observation) permits a more robust analysis compared to single arm intervention studies (e.g., all MRD positive patients receive additional therapy). Again, in certain circumstances, the MRD assay may represent a significant risk device, which requires further discussion with the FDA and may require an IDE. As an endpoint, MRD can provide useful information regarding the activity of the investigational therapeutic. However, there are several statistical and clinical considerations when using MRD as a clinical trial endpoint. As such, the Agency recommends that sponsors discuss with the Agency the use of MRD when considering it as a key secondary or primary endpoint.

The FDA guidance on MRD states, “the strength of evidence to support surrogacy depends on 1) the biological plausibility of the relationship, 2) demonstration in epidemiological studies of the prognostic value of the surrogate endpoint for the clinical outcome, and 3) evidence from clinical trials that the treatment effects on the surrogate endpoint correspond to effects on the clinical outcome” (118). The biological plausibility and prognostic value of MRD are well understood and have been supported by multiple studies. What remains to be elucidated is the evidence from clinical
trials regarding the relationship between the treatment effect on MRD and the treatment effect on clinical outcomes of interest. There are current efforts to gather evidence from clinical trials to allow for further evaluation of the treatment effect relationship between MRD and clinical outcomes such as PFS and OS on both a trial-level and at an individual patient-level. These data will supplement our understanding of MRD and how to most effectively use MRD to expedite drug development.

With development of more sensitive assays, there may be opportunity for better disease quantification and discrimination of patients that are in CR and a potential for use of MRD as a drug development tool. However, data collection and assay performance characteristics should be of sufficient rigor and completeness to allow for comprehensive assessments. Including MRD assessments in prospective MM clinical trials can help strengthen the available evidence for the use of this biomarker in MM.

### 3.2 Industry Perspectives on the Regulatory Importance of MRD as a Surrogate Endpoint

There have been many advancements in the development of novel and more effective therapies for the treatment of MM in recent years, providing meaningful clinical benefit and prolonging patient survival. This has resulted in an increasingly challenging situation for bringing new drugs to patients with MM in a timely manner. This challenge is especially true in the case of frontline trials, in which the time to reach the traditional endpoints of PFS or OS is becoming prohibitively long as patients are experiencing progressively longer PFS and OS. Despite these advances, there continues to be a significant unmet medical need in patients with MM. Hence, novel therapies and regimens continue to be required to further enhance PFS and OS and to ultimately lead to a cure. Given the dramatic improvements in PFS with current therapies, clinical trials will require formidable sample sizes and unrealistic follow-up time to detect clinically meaningful treatment effects with sufficient statistical power. This in turn is making it increasingly difficult for companies to conduct clinical trials using traditional clinically-relevant endpoints to achieve regulatory approval. Conversely, if an intervention is not likely to be beneficial, patients may stay on therapy for a long period before these studies reveal the lack of benefit. In short, using PFS or OS as a primary endpoint is becoming unsustainable. Moreover, because the MM landscape is continuously evolving, the longer these clinical trials take to reach their endpoints, the more likely it is that the comparator arms become obsolete by the time the studies are analyzed. In order to maintain the speed and progress of new drug development in MM, there is a need for a surrogate endpoint that 1) provides an earlier assessment of efficacy and 2)
correlates strongly with clinically relevant endpoints. Improved methods to evaluate response in support of early registration and access to therapies are needed. Evaluation of MRD has come to the forefront of these efforts in MM, where MRD negativity status is associated with significantly improved survival outcomes.

While the need for a surrogate endpoint is most urgent in frontline trials, MRD endpoints will similarly aid patients and drug development efforts in the relapsed/refractory MM (RRMM) setting. A considerable amount of MRD data has been prospectively generated and is available from numerous MM clinical trials in both the frontline and RRMM settings, with many more trials currently underway collecting MRD data. MRD negativity is the primary or co-primary endpoint for the early assessment of response in many currently ongoing clinical trials. As such, MRD assessment of response as a primary endpoint in MM offers the potential to promptly deliver new therapies to patients with an unmet need.

It would be beneficial for regulatory agencies to use existing data from completed MM trials to provide industry with guidance on specific timepoints that can be used in prospective MM trials for evaluating MRD status. Such guidance will of course evolve, but if we wait for future clinical trials to provide definitive validation of MRD as a surrogate endpoint, valuable years will be lost as we wait for these studies to progress and these data to mature. Often, novel drugs are most likely to benefit MM patients in early lines more than in the late lines of treatment, where they are first evaluated, and the availability of MRD as a surrogate endpoint will expedite these clinical trials and their application. It is vitally important for the continuation and advancement of drug development in MM that regulatory agencies and industry collaborate in the near-term to establish a faster, accepted, surrogate endpoint for the future treatment of MM patients.

4.0 Considerations for clinical use of MRD in different patient populations

The accumulated data over the past decade, especially in the recent years with introduction of highly effective therapeutic combinations, have clearly shown the value of MRD testing in MM. As described earlier in the manuscript, MRD testing in MM has several important roles to play. At any stage in the disease evolution, achievement of MRD negativity will predict for a better outcome compared to patients at a similar stage who have not achieved the same depth of response with any given therapy. As stated earlier, clinicians are starting to incorporate MRD determination in routine clinical
management decisions. In this section, we have used patient scenarios to outline the potential clinical utility of MRD, and remaining gaps in our knowledge to be addressed in ongoing and future clinical trials. The aim here is more to highlight the potential of MRD in various disease settings rather than making specific recommendations, something that is starting to being addressed through international harmonization efforts (119).

4.1 Smoldering Multiple Myeloma

The standard of care and the general approach is not to treat smoldering multiple myeloma (SMM) patients. Translational and clinical research is ongoing to identify those patients needing intervention, and what regimens would be the best to prevent disease progression and end-organ damage, along with deeper responses and minimal toxicities. In SMM, MRD testing is currently only performed in a clinical trial setting (Fig. 1).

4.2 Newly-Diagnosed Multiple Myeloma

The current standard of care for patients with newly diagnosed MM who are eligible to undergo an ASCT is to have four to six cycles of induction therapy with a triplet containing a proteasome inhibitor and an IMiD, followed by a single ASCT and lenalidomide maintenance following transplant. Recent trials have focused on development of quadruplets with addition of monoclonal antibodies to the PPI-IMiD triplets.

The role of stem cell transplantation and lenalidomide maintenance for MM has been based on large randomized trials that were performed both in the context of older therapies as well as newer induction regimens. There is a possibility that MRD status at the end of induction therapy can help guide this decision-making, and similarly, that we can decide on the use of maintenance or the specific regimen to be used for maintenance based on the MRD status. However, at this time, data from prospective clinical trials are not available in order to make truly informed decisions based on MRD testing. Regardless, this is an issue that clinicians encounter routinely in daily practice as exemplified in (Fig 2-4).

First remission following induction is on average the longest period of remission that patients will experience. Quality of life has been reported to be better in first remission, and large patient survey
data have reported this using PROM tools. Lenalidomide is now an established standard-of-care as post-transplant maintenance, but 36% of patients stopped lenalidomide maintenance treatment in the Myeloma XI trial due to adverse events or personal preference. It is therefore important to have sensitive reliable tools like MRD to assess disease during treatment-free monitoring (Fig. 5).

### 4.3 Relapsed Refractory Myeloma

Novel immune therapies have a remarkable ability to achieve rapid MRD negative complete responses even in the context of multiply relapsed, genetically high risk disease. The value of MRD negativity as a surrogate marker in RRMM may be context dependent and vary with stage of disease and treatment modality (Fig 6).

### 5.0 Conclusion, summary of recommendations and call to action

The development of novel agents has transformed the treatment paradigm for MM, with MRD negative response now achievable both in newly diagnosed and relapsed disease. NGS and NGF are now most commonly utilized to measure BM MRD, along with PET/CT imaging to assess extramedullary disease. However, additional technologies including mass spectrometry-based paraprotein analyses, cfDNA, scRNA-seq, as well as whole body DWI MRI and novel tracers for imaging are rapidly evolving and may be used to measure MRD in the future. Section 3 of this article outlines regulatory considerations for both MRD assessment and incorporation into clinical trials. Although multiple retrospective individual patient and clinical trial level meta-analyses have already shown and will continue to assess MRD as a surrogate for patient outcome, designing current and future trials incorporating these regulatory considerations is necessary to assure continued rapid new drug development in MM. The current value of MRD to inform clinical patient care is also illustrated using real world cases of patients with smoldering MM, newly diagnosed transplant eligible MM, newly diagnosed transplant ineligible MM, and relapsed refractory MM, in each case summarizing what is known and key questions to be addressed in clinical trials. Most importantly, broad input from international academic clinical researchers and caregivers, FNIH, FDA, biotechnology and pharmaceutical industries formulated this white paper and call to action and represent the team necessary to implement these recommendations and assure progress utilizing MRD both as a regulatory endpoint and to guide clinical care. The pace of advances in targeted and immune therapies in MM is unprecedented, and this collaborative effort, inspired by a shared
commitment to patients, will assure that these advances translate to clinical trials leading to regulatory approval of novel treatments and continued improvement in patient outcomes.

### Case 1 - Smoldering Myeloma

| Case Description | A 63-year-old patient was diagnosed three years ago with IgA kappa smoldering myeloma. Bone marrow biopsy and aspirate showed 20% infiltration by monoclonal CD138+ plasma cells. Karyotype and FISH studies revealed hyperdiploid genotype and 1q gain. Laboratory revealed an IgA kappa M protein 1.55 g/dL. Kappa light chains 696 mg/L, and free light chain ratio 81. The patient was otherwise asymptomatic with no myeloma defining events. The patient enrolled in a 2-year clinical trial for treating smoldering myeloma patients, including an induction phase of nine cycles and maintenance phase for 15 cycles. The patient achieved a complete response (CR) by the end of cycle nine, confirmed with bone marrow biopsy, and MRD assessed by next-generation sequencing was negative at 10-6 threshold. The patient completed the clinical trial in February 2019, and remains in CR which persists to July 2020. |
| What we know with regards to MRD | Two recent trials tested MRD status in response to different regimens in SMM, and reported the results in ASH 2019. In one study, MRD negative state was present in 63% patients who achieved CR (n=51) after induction and consolidation, by next-generation flow cytometry assay. In the other study, MRD negative state was present in 69% patients who achieved CR (n=13) after nine cycles of induction by next-generation sequencing of VDJ rearrangement assay. |
| Key questions we need to answer | MRD status has been recently tested in the setting of clinical trials in SMM 1,2. However, these trials are still ongoing, and longer follow up is needed to fully assess the association between MRD negative status and progression-free survival. Data from such studies, once mature, will help in the management of SMM by identifying regimens that lead to better disease control and deeper responses. Moreover, they will help identify the genomic and cytogenetic SMM profiles that would need different treatment strategies, rather than using one approach for all disease subtypes. |

---

Case 2 - Newly Diagnosed MM Transplant Eligible - Normal Risk

| Case Description | A 64-year-old man presented with back pain and was found to have L3 compression fracture and multiple lytic lesions on whole body CT scan. Laboratory revealed IgG Kappa M spike of 3.2 gram per deciliter, elevated Kappa and Kappa: lambda ratio, serum albumin 3.7 mg/dL and beta two microglobulin of 4.8 mg/L; LDH, serum calcium, and creatinine were normal. Bone marrow biopsy showed 50% plasma cells, with translocation 11;14 on FISH. He was diagnosed with revised ISS stage I MM disease and began lenalidomide bortezomib, and dexamethasone (RVD) therapy. He achieved a complete response after four cycles of RVD therapy, underwent stem cell collection, received 200 mg/m2 melphalan followed by reinfusion of his stem cells. At 100 days post-transplant, he was MRD negative by next generation flow cytometry. The patient wanted to know if he would benefit from receiving maintenance therapy, given that he is MRD negative at this time. |
| What we know with regards to MRD | There is no definitive data from prospective clinical trials to inform whether achievement of MRD negativity prior to transplant can improve long term outcomes of MM patients, including overall survival. And while the role of lenalidomide maintenance therapy has been demonstrated in multiple Phase III trials, and in meta-analyses, it remains unclear whether we can decide on the use and type of maintenance based on the MRD status post-transplant. Phase III trials are needed to determine whether MRD negativity can be an indicator to discontinue maintenance therapy. |
| Key questions we need to answer | In patients with standard risk multiple myeloma who have excellent survival with current treatments, the lack of data from prospective clinical trials demonstrating a survival benefit of altering therapy to achieve MRD negativity this approach can potentially expose patients to unnecessary therapy and increase toxicity. At least one European trial has shown benefit for additional consolidation therapy after ASCT prior to initiating maintenance, although this has not been consistently demonstrated in all clinical trials. Quadraplet induction regimens have been associated with deeper responses prior to stem cell transplant, but there is limited data on long term outcomes, especially overall survival. It remains unclear if all patients will benefit form use of 4-drug regimens or whether we can develop response adapted strategies where the 4th drug is added for failure to reach a certain depth of response with 3 drugs over a defined period of time. |

## Case 3 - Newly Diagnosed MM Transplant Eligible - High Risk

### Case Description
A 54-year-old man presented with back pain. Laboratory revealed hemoglobin of 10.2 g/dL, normal serum calcium and creatinine, IgG kappa M spike 2.1 gm/L, kappa 36 mg/dL, lambda 0.29 mg/dl, 24-hour urine 240 mg M spike. Skeletal survey revealed numerous lytic lesions. Bone marrow showed 40% PCs, with t(4;14) and chromosome 1q amplification on FISH. He was treated with VRd for 4 cycles, achieved VGPR, and then received 200 mg/m2 melphalan followed by autologous SCT and achieved CR. Marrow evaluation with NGS showed persistent MRD. The role of additional consolidation and or a tandem autologous stem cell transplantation was discussed in detail with the patient.

### What we know with regards to MRD
High risk patients do not benefit from current treatment approaches. Given emerging data regarding the improved outcomes in high risk myeloma associated with achieving MRD negativity\(^1,2\), one can make an argument for routine use of MRD testing in these patients, even outside of clinical trials. The observation that the magnitude of benefit associated with MRD negativity appears substantially higher for the high-risk group compared with standard risk myeloma, coupled with the risk of continuing with current treatment approaches, makes this decision easier.

### Key questions we need to answer
Several important MRD questions need to be answered in carefully designed clinical trials of high risk myeloma. In particular, the importance of reaching MRD negativity, and the need for changing therapy based on not reaching a predefined depth of response by a defined time, are important considerations to improve outcome of high-risk patients. The role of sustained MRD negativity is key for patients with high-risk MM.

---

### Case 4 - Newly Diagnosed MM Transplant Ineligible

**Case Description**
An 84-year-old man with type 2 diabetes well controlled with oral medications and atrial fibrillation was symptomatic and found to have mild anemia (hemoglobin 10.4 g/dL). Evaluation revealed an IgAK spike 3.2 g/dL with low IgM/IgG serum levels, and serum free kappa light chain ratio 100. Whole body low dose CT revealed several lytic lesions, with 2 dorsal and 3 lumbar vertebral fractures. Bone marrow biopsy showed 50% plasma cells, and FISH revealed del13 and t(11;14). He is a retired engineer who lives alone in a third floor apartment, with no lift available. He began lenalidomide-dexamethasone, but dexamethasone was poorly tolerated and stopped after 8 cycles. Recurrent diarrhea required lenalidomide dose reduction to 10 mg/day from cycle 10. He achieved a VGPR after one year of treatment, and his PS definitely improved.

**What we know with regards to MRD**
Although mostly studied in transplant-eligible patients, MRD negativity is also achievable in transplant-ineligible patients. A retrospective analysis of concomitant IFE and MRD testing in 289 patients with MM demonstrated 20% 1-year probability of progressive disease if both MRD and IFE negative versus 40% in the MRD negative, IFE positive group\(^1\). Persistent M-protein despite MRD negativity predicts for a shorter time to progression. Some patients who are IFE positive do ultimately become IFE negative owing to the prolonged M protein half-life and clearance of the M-protein, and there are trends towards improved TTP in those who ultimately become IFE negative. While MRD can be a powerful prognostic tool, other patient characteristics, such as frailty, can predict mortality in the elderly MM population. The Geriatric Assessment can predict both toxicity and mortality. Therapeutic decisions must be based on the collective data available for a patient, weighing the benefits of increased depth of response versus increased treatment-related toxicity.

**Key questions we need to answer**
We need to incorporate MRD testing into clinical trial design in newly diagnosed transplant-ineligible patients in order to determine the optimal timepoints for MRD evaluation, if MRD evaluation is needed in all patients achieving a specific response, and potential impact of MRD on treatment decisions. These studies will provide an evidence-based foundation for using MRD status to inform decisions regarding treatment duration and discontinuation.

---

## Case 5 - Treatment-Free Monitoring

| Case Description | A 59 year old artistic director was diagnosed with ISS stage 1 IgG kappa myeloma. He presented with back pain, and PET CT showed FDG avid fractures of thoracic vertebrae T7 and T8. He had mild anaemia (hemoglobin 10.1 g/dL), with normal calcium and renal function. Bone marrow biopsy showed 35% plasma cells, with FISH testing showing hyperdiploidy. Serum electrophoresis showed an M-protein spike of 3.4 g/dL, serum free kappa/lambda light chain ratio was 35.2. He was treated with VTD induction, and developed grade 1 peripheral neuropathy and a deep vein thrombosis treated with anticoagulation. He achieved CR with normal FDG PET-CT scan and then received high dose melphalan and ASCT. At 3 months post transplant MRD was negative, assessed by Flow cytometry at a sensitivity of 10-5. Lenalidomide maintenance was started about 4 months post transplant, but was discontinued after 6 months due to gastrointestinal side effects. He is currently on a treatment free monitoring period and has had a bone marrow annually with ongoing MRD negativity, along with 3 monthly blood work which confirms ongoing CR. He has been able to engage with normal day to day activities and work routine. |
| What we know with regards to MRD | First remission following induction is on average the longest period of remission patients experience\(^1\). Quality of life has been reported to be better in first remission and large patient survey data have reported this using PROM tools\(^2\). Myeloma has the potential to relapse during treatment free periods, and patients therefore require monitoring to include blood work, clinical evaluation, MRD assessment, and whole body imaging. |
| Key questions we need to answer | It is unclear what data is needed to monitor patients who prefer to stop therapy either due to personal preference or due to adverse events. If patients have achieved less than CR, then blood work alone as a standard of care is reasonable. In patients who are in CR, tools to monitor MRD by Flow or NGS and imaging are reasonable to consider. The frequency of application of these tools, and whether both tools should be applied together, requires further evaluation in prospective studies. Currently patients start treatment for MM when IMWG criteria for relapse are met. Future trials will evaluate feasibility and benefit of starting treatment upon change of MRD status. |

---

| **Case Description** | A 63 year old man presented with fatigue and lower back pain. He was found to have Hct 28% Creat 1.8mg/dL, Calcium 11 mg/dL and diffuse lytic bone disease. Serum IgG kappa was 6gm/dL, and bone marrow showed 80% plasma cells with t(11;14). He was treated with lenalidomide, bortezomib, and dexamethasone followed by high dose melphalan, ASCT, and lenalidomide maintenance therapy for three years. Increasing back pain, fatigue, and dyspnea on exertion develop on maintenance treatment. Restaging reveals IgG lambda 2.5g gm/dL, Hct 28%, creat 1.8 mg/dL, and Ca 10.0mg/dL. BM reveals 40% plasma cells, with t(11;14) and del17p. PET/CT reveals multiple new sites of uptake in thoracic and lumbarosacral spine. He is treated with daratumumab, carfilzomib, and dexamethasone and achieves a partial response lasting only 6 months, and then again develops rising IgG lambda protein and new vertebral compression fractures. Due to his t(11:14) translocation, he receives venetoclax and carfilzomib therapy, and achieves a partial response lasting 10 months. Again relapse is noted with rapidly rising IgG lambda and progressive anemia, bone disease, and hypercalcemia. He is treated with anti-BCMA CAR-T cell protocol therapy, and achieves a bone marrow and imaging MRD negative complete response within one month of therapy that lasts for 9 months. |

| **What we know with regards to MRD** | Significant responses in patients who literally have exhausted all other treatment options are now being seen in novel immune treatments, including CAR-T cell and bispecific T-cell engager treatments. However, to date the duration of response even in those patients who achieve MRD negativity is only 8 to 11 months. Ongoing studies are therefore attempting to prolong these responses by modifying the CAR-T to enhance its activity and survival post infusion, selecting for memory stem T-cells, and treating patients earlier in their disease course. |

| **Key questions we need to answer** | Ongoing meta-analyses at both a clinical trial and individual patient level are assessing the utility of MRD negativity as a surrogate endpoint predictive of outcome in patients at various stages of disease including RRMM, with distinct genetic subtypes, and receiving various therapies. |
